26 **Abstract**

27 We present here a tectonic-geodynamic model for the generation and flow of partially molten rocks and for
28 magmatism during the Variscan orogenic evolution from the Silurian to the late Carboniferous based on a synthesis
29 of geological data from the French Massif Central. Eclogite facies metamorphism of mafic and ultramafic rocks
30 records the subduction of the Gondwana hyperextended margin. Part of these eclogites are forming boudins-
31 enclaves in felsic HP granulite facies migmatites partly retrogressed into amphibolite facies attesting for

32 continental subduction followed by thermal relaxation and decompression. We propose that HP partial melting
33 has triggered mechanical decoupling of the partially molten continental rocks from the subducting slab. This would
34 have allowed buoyancy-driven exhumation and entrainment of pieces of oceanic lithosphere and subcontinental
35 mantle. Geochronological data of the eclogite-bearing HP migmatites points to diachronous emplacement of
36 distinct nappes from middle to late Devonian. These nappes were thrust onto metapelites and orthogneisses
37 affected by MP/MT greenschist to amphibolite facies metamorphism reaching partial melting attributed to the late
38 Devonian to early Carboniferous thickening of the crust. The emplacement of laccoliths rooted into strike-slip
39 transcurrent shear zones capped by low-angle detachments from c. 345 to c. 310 Ma is concomitant with the
40 southward propagation of the Variscan deformation front marked by deposition of clastic sediments in foreland
41 basins. We attribute these features to horizontal growth of the Variscan belt and formation of an orogenic plateau
42 by gravity-driven lateral flow of the partially molten orogenic root. The diversity of the magmatic rocks points to
43 various crustal sources with modest, but systematic mantle-derived input. In the eastern French Massif Central,
44 the southward decrease in age of the mantle- and crustal-derived plutonic rocks from c. 345 Ma to c. 310 Ma
45 suggests southward retreat of a northward subducting slab toward the Paleotethys free boundary. Late
46 Carboniferous destruction of the Variscan belt is dominantly achieved by gravitational collapse accommodated by
47 the activation of low-angle detachments and the exhumation-crystallization of the partially molten orogenic root
48 forming crustal-scale LP migmatite domes from c. 305 Ma to c. 295 Ma, coeval with orogen-parallel flow in the
49 external zone. Laccoliths emplaced along low-angle detachments and intrusive dykes with sharp contacts
50 correspond to the segregation of the last melt fraction leaving behind a thick accumulation of refractory LP felsic
51 and mafic granulites in the lower crust.

52 This model points to the primordial role of partial melting and magmatism in the tectonic-geodynamic evolution
53 of the Variscan orogenic belt. In particular, partial melting and magma transfer (i) triggers mechanical decoupling
54 of subducted units from the downgoing slab and their syn-orogenic exhumation; (ii) the development of an
55 orogenic plateau by lateral flow of the low-viscosity partially molten crust; and, (iii) the formation of metamorphic
56 core complexes and domes that accommodate post-orogenic exhumation during gravitational collapse. All these
57 processes contribute to differentiation and stabilisation of the orogenic crust.

93 1. Introduction

94
95 Migmatites and granites are the main constituents of the continental crust and their petrogenesis and emplacement
96 are intimately linked to orogenic evolution (Brown, 2001; Foster et al., 2001; Sawyer, 1998; Sawyer et al., 2011;
97 Thompson and Connolly, 1995; Vanderhaeghe, 2009; Weinberg, 2016; Závada et al., 2018). Various heat sources
98 have been proposed to cause high-temperature metamorphism and partial melting of orogenic roots comprising an
99 increase in radioactive heat production of the thickened crust, an increase in the basal heat flux associated with
100 delamination of the lithospheric mantle and heat advection through the emplacement of mantle-derived magmas
101 (Annen and Sparks, 2002; England and Thompson, 1984, 1984; Henk et al., 2000; Houseman et al., 1981; Ueda
102 et al., 2012; Vanderhaeghe et al., 2003; Vanderhaeghe and Duchêne, 2010). In turn, partial melting has a profound
103 impact on the rheology at the scale of the rock and at the one of the entire crust (Brown and Solar, 1998; Gébelin
104 et al., 2006; Rosenberg, 2001; Schulmann et al., 2008; Solar et al., 1998; Vanderhaeghe, 2009; Vanderhaeghe and
105 Teyssier, 2001; Vigneresse et al., 1996), which is expressed by an intimate link between deformation and
106 melt/solid segregation (Brown and Rushmer, 1997; Brown and Solar, 1998; Hasalová et al., 2008; Hasalova et al.,
107 2011; Sawyer, 1994; Vanderhaeghe, 1999; Weinberg et al., 2013; Weinberg and Searle, 1998). Partial melting
108 potentially triggers mechanical decoupling of the subducted continental crust from the downgoing slab as it has
109 been proposed for example in the Norwegian Caledonides or the Variscan Bohemian Massif (Gordon et al., 2016;
110 Labrousse et al., 2011; Závada et al., 2018). Partial melting has also been identified as the key parameter
111 controlling lateral flow of the deep root of orogenic belts through the activation of vertical shear zones (Solar et
112 al., 1998; Weinberg and Mark, 2008) leading to the formation of orogenic plateaux (Cagnard et al., 2006; Chardon
113 et al., 2009; Gerbault et al., 2005; Vanderhaeghe et al., 2003; Vanderhaeghe and Teyssier, 2001). Finally, the
114 ubiquitous presence of large domes cored by migmatites in the exhumed roots of orogenic belts (Vanderhaeghe,
115 2009; Whitney et al., 2004) as well as the spatial-temporal correlations between the emplacement of granitic
116 laccoliths and the activation of low-angle detachments (Lister and Baldwin, 1993; Searle et al., 2009;
117 Vanderhaeghe, 1999; Whitney et al., 2013) suggest that the presence of a partially molten crust and the migration
118 of granitic melts controls the behaviour of the orogenic crust during orogenic gravitational collapse.

119
120 The Variscan belt of Western Europe (Fig. 1) has long been recognized as particularly rich in migmatites and
121 granitoids (e.g. Zwart, 1967) and is thus the perfect target to investigate the impact of partial melting and
122 magmatism on orogenic evolution. The large spread of radiochronological ages obtained on migmatites and
123 magmatic rocks (from c. 390 Ma to c. 290 Ma) and the wide variety of petrological and geochemical characteristics

124 of the magmatic rocks indicate that the 100 Ma long tectonic history of the Variscan belt has been punctuated by
125 the emplacement of magmas implying the contribution of both, the crust and the mantle (Bussien et al., 2008;
126 Couzinié et al., 2013; Cuney et al., 1990; Laurent et al., 2017; Letterrier, 1978; Solgadi et al., 2007; von Raumer
127 et al., 2014). In addition to the identification of the sources and geodynamic context of these magmas, arises the
128 question of the impact of low-viscosity and low-density silicate melts on the dynamic evolution of the Variscan
129 orogen.

130
131 Despite the significant exposure of migmatites and granitoids, their implication on the tectonic evolution of the
132 Variscan belt has not been fully explored, to the noticeable exceptions of some papers on the French Massif Central
133 (Burg and Vanderhaeghe, 1993; Costa and Rey, 1995; Malavieille et al., 1990; Vanderhaeghe et al., 1999) and
134 Central Iberia, the Vosges, and Bohemia (Henk, 2000; Henk et al., 2000; Lardeaux et al., 2014; Rubio Pascual et
135 al., 2016; Schulmann et al., 2008, 2014). The goal of this paper is to discuss the impact of partial melting and
136 magmatism on the tectonic evolution of the Variscan orogenic belt of Western Europe based on a synthesis of
137 structural, petrological, geochemical, geochronological and sedimentological data available for the Variscan
138 basement of the French Massif Central. This regions offers a unique section through the Variscan crust that
139 recorded, from Silurian to Permian, a prolonged history of burial and exhumation associated with the construction
140 and destruction of the belt, respectively. The tectonic evolution is particularly marked by the generation of
141 migmatites under HP, MP and LP metamorphic conditions and by varied plutonic rocks emplaced from the middle
142 Devonian to the early Permian. This history is complemented by the P-T-t record of lower crustal xenoliths brought
143 back to the surface by Cenozoic volcanoes and by unmetamorphosed to low-grade volcano-sedimentary series
144 deposited from the middle Devonian (Givetian) to the Permian that constrain the topographic evolution of the belt.

145
146 In this paper, we propose a new geodynamic model for the generation and flow of partially molten rocks and
147 magmas during orogenic evolution from construction by tectonic accretion of subducted continental units followed
148 by lateral growth of the orogenic belt associated with construction of an orogenic plateau and eventually to
149 gravitational collapse. This geodynamic model is also nourished by new data recently published in companion
150 papers comprising (i) Lu-Hf tracing of gneisses and plutonic rocks (Chelle-Michou et al., 2017; Couzinié et al.,
151 2017, 2019), (ii) U-Pb dating of zircon and monazite by LA-ICP-MS on the Carboniferous plutonic rocks (Chelle-
152 Michou et al., 2017; Laurent et al., 2017) and (iii) a detailed petrogenetic model for these granitoids (Moyen et al.,
153 2017).

154

2. Geology of the French Massif Central: a window through the Variscan belt

2.1. The Variscan belt: continental blocs, oceanic sutures, allochthonous terranes and paleogeographic reconstructions

The Variscan belt has been first defined as a post-Cambrian and pre-Permian mobile belt based on analysis of stratigraphic unconformities, structures and nappes (Bertrand, 1887; Suess, 1883). It is extending from East Asia to the tip of South America running through Central Europe and along the edges of North America (Matte, 2001). Paleomagnetic data indicate that the Variscan belt formed as a consequence of the convergence between Laurussia (Laurentia + Baltica) and Gondwana resulting in the Pangea supercontinent (Scotese and McKerrow, 1990; Tait et al., 2000; Unrug, 1997). However, the number of oceanic sutures and the former sizes of the oceanic basins are discussed as developed below.

Pioneer work correlating data from the eastern (Bohemia) and western (Iberia) terminations of the belt led to (i) the definition of the main geological-tectonic zones, (ii) the identification of the principal Paleozoic tectonic events based on the relationship between structures and Ediacaran to Carboniferous sedimentary deposits in the external zone and along the foreland, and (iii) the recognition of high-grade nappes in the internal zone (Demay, 1948; Gaertner, 1937; Gèze, 1949; Kossmat, 1927; Stille, 1924). The relationship between sedimentation and deformation, best exposed along its external domains, allowed the identification of continental blocks such as Avalonia, Armorica, Saxo-Thuringia, Barrandia and Brunia, all of which preserve Cambrian unconformities more or less affected by Variscan deformation and metamorphism (Franke, 1989, 2000; Franke and Engel, 1986; Kroner and Romer, 2013; Matte, 1986, 1991). These continental blocs are separated by oceanic sutures marked by ophiolitic assemblages or mélanges. All authors agree on the Rheic suture, also called the Lizard-Rheno-Hercynian suture, that corresponds to the former Rheic Ocean, to the south of Avalonia and to the north of Saxo-Thuringia and Armorica (Fig. 1) (Ballèvre et al., 2014; Franke, 2000; Franke et al., 2017; Matte, 1991). The nature of the terranes and the presence of sutures south of Armorica is however debated. Despite uncertainties, we favor the existence of multiple sutures (designated as “secondary sutures” on figure 1) based on (i) the presence of ultramafic and mafic high-pressure rocks of different ages at different structural levels (Ballèvre et al., 2009; Berger et al., 2010a; Bosse et al., 2000; Dubuisson et al., 1989; Faure et al., 1997; Girardeau et al., 1986; Lardeaux, 2014; Lardeaux et al., 2014; Lotout et al., 2018), and (ii) the occurrence of remnants of subordinate Devonian rift and/or oceanic basins (Sider and Ohnenstetter, 1986; Skrzypek et al., 2012).

187 In the French Massif Central, until the middle of the 20th century, the prevailing model attributed the high-grade
188 granitic-gneisses to a crystalline basement and the paragneisses and schists to a sedimentary cover deposited from
189 the Neoproterozoic throughout the Paleozoic (Jung, 1953; Roques, 1971). In the absence of geochronological data,
190 metamorphism was considered as polycyclic, the basement being metamorphosed during the Neoproterozoic, and
191 then, together with its sedimentary cover, during the Caledonian and the Variscan orogenies (Chenevoy and Ravier,
192 1971; Forestier, 1961; Roques, 1971). This view has been profoundly modified first by the results of absolute
193 dating demonstrating ubiquitous Variscan reworking (Duthou et al., 1994; Gebauer et al., 1981; Pin and Lancelot,
194 1982; Rolin et al., 1982). Another turning point was to interpret the felsic/mafic gneisses with a tholeiitic signature,
195 defined as the Leptynite-Amphibolite Complex (LAC), as remnants of ophiolites (Briand et al., 1988; Briand and
196 Piboule, 1979; Cabanis et al., 1983; Dubuisson et al., 1989; Forestier, 1961; Maillet et al., 1984; Mercier et al.,
197 1985; Piboule and Briand, 1985; Pin, 1990). In the Armorican Massif, ophiolites define the Medio-European suture
198 also referred to as the Galicia-South Brittany suture, or the Eo-Variscan suture (Ballèvre et al., 2009; Bernard-
199 Griffiths and Cornichet, 1985; Faure et al., 1997; Hanmer, 1977). This suture corresponds to the former Medio-
200 European Ocean (also designated as the Galicia-Massif Central Ocean or the Paleotethys Ocean) that is located to
201 the south of the Armorica-Barrandia continental block (Matte, 1986, 2001; Pin, 1990; Stampfli et al., 2013) (Fig.
202 1).

203
204 Based on this analysis, most authors agree that the Variscan belt of Western Europe results from tectonic accretion
205 of the Avalonia and Armorica ribbon-shaped continental terranes and the closure of intervening oceanic basins,
206 marked by (i) the Iapetus-Tornquist suture north of Avalonia, (ii) the Rheic/Rheno-Hercynian suture between
207 Avalonia and Armorica (Matte, 2001; von Raumer et al., 2003) and (iii) the Medio-European suture between
208 Armorica and Gondwana (Matte, 1986, 2001; Pin, 1990; Stampfli et al., 2013) (Fig. 2 a, b). All models invoke
209 closure of the Iapetus Ocean during the Ordovician concomitantly to the rapid opening of the Rheic Ocean (e.g.
210 Hamilton and Murphy, 2004) by reactivation of a Neoproterozoic suture along the northern Gondwana margin
211 (Linnemann et al., 2007). The driving force for this oceanisation has been attributed either to slab pull from the
212 northward subducting Iapetus (Murphy et al., 2006) or to roll-back of a southward subducting slab beneath the
213 Gondwana margin (Martínez Catalán et al., 2009). Paleogeographic reconstruction differ for the early Ordovician
214 period with regard to the position of Armorica that has implications on the existence and size of the Medio-
215 European Ocean (Ballèvre et al., 2009; Edel et al., 2018; Faure et al., 2008; Kroner and Romer, 2013; Lardeaux,
216 2014; Lardeaux et al., 2014; Martínez Catalán et al., 2007, 2009; Matte, 2001; Nance et al., 2010; Schulmann et
217 al., 2014; Shail and Leveridge, 2009; Skrzypek et al., 2014; Stampfli et al., 2013; Tait et al., 2000; Torsvik et al.,

218 2012). Indeed, sedimentologic and paleontological data lead to paleogeographic reconstructions indicating a
219 position close to the South Pole for Gondwana together with Avalonia and Armorica, and between the tropics and
220 the equator for Laurentia and Baltica (Fortey and Cocks, 2003; Paris and Robardet, 1990; Robardet et al., 1993;
221 Robardet, 2003). This is consistent with paleomagnetic data indicating an Iapetus Ocean at least 3000 km wide
222 (Cocks and Torsvik, 2002; Hamilton and Murphy, 2004; Tait et al., 2000). On the other hand, some paleomagnetic
223 data indicate that Armorica remained attached to the Gondwana margin until the Devonian (Kössler et al., 1996),
224 which is consistent with the continuity of benthic faunas from Armorica to the northern margin of Gondwana
225 (Robardet, 2003) while other paleomagnetic data indicate that Armorica moved toward Laurussia during the
226 Ordovician (Tait et al., 2000), implying closure of the Rheic Ocean and opening of a 2000-3000 km wide Medio-
227 European Ocean (Cocks and Torsvik, 2006; Shaw and Johnston, 2016; Tait et al., 1997). As a result, two
228 paleogeographic reconstructions clash, one favoring a large Medio-European Ocean between Gondwana and a
229 continental ribbon including Armorica (Domeier, 2016; Domeier and Torsvik, 2014; Matte, 2001; Stampfli and
230 Borel, 2004; von Raumer et al., 2003), while the other consider at most a small immature rift in this region and
231 infer that the large oceanic realm is the Rheic Ocean (Kroner and Romer, 2013; Martínez Catalán et al., 2007;
232 Nance et al., 2010)(Fig. 2 c, d). On the other hand, tectonic reconstructions based on geological data implying
233 multiple rifts and/or oceanic basins in between Armorica and Gondwana (Dubuisson et al., 1989; Faure et al., 1997;
234 Girardeau et al., 1986; Lardeaux, 2014; Lardeaux et al., 2014), correspond to an intermediate proposition.

235

236 **2.2. The main lithologic-tectonic units of the French Massif Central**

237

238 The French Massif Central is one of the largest exposures of the Variscan belt of Western Europe. Its geology is
239 synthesized with reference to 1:1 000 000 scale map (Chantraine et al., 1996, 2003) and to the lithologic-tectonic
240 units defined on the basis of their distinct lithological, structural, metamorphic and geochronological record (Burg
241 and Matte, 1978; Faure et al., 2009a; Lardeaux, 2014; Ledru et al., 1989; Matte, 1986; Quenardel et al., 1991).
242 According to these authors, the French Massif Central is made of (i) low- to high-grade metamorphic nappes with
243 a Devonian to Carboniferous tectonic record, (ii) late Devonian to late Carboniferous plutonic rocks, (iii) late
244 Devonian to Carboniferous volcanic and carbonate to clastic sedimentary rocks affected by low-grade
245 metamorphism, and (iv) unconformable late Carboniferous and Permian detrital sediments (Fig. 3). The French
246 Massif Central is subdivided into a western part and an eastern part by the NNE-SSW trending Sillon Houiller
247 Fault (Arthaud and Matte, 1975; Feybesse, 1981) (Fig. 3). The latter crosscuts a set of NW-SE to NNW-SSE
248 trending dextral shear zones that is particularly well-developed in the western part of the French Massif Central

249 and connects to the South Armorican shear zone (Gébelin et al., 2007; Lerouge and Quenardel, 1988). The nappe
250 pile is also cross-cut by low-angle detachements (Bellot, 2007; Burg et al., 1993; Faure, 1995; Gardien et al., 1997;
251 Malavieille et al., 1990).

252

253 *Metamorphic nappes*

254

255 The interpretation of the LAC as a suture marking the boundary between an Upper Gneiss Unit (UGU) and a
256 Lower Gneiss Unit (LGU) led to the reinterpretation of the structure of the FMC in terms of nappe stacking (Burg
257 and Matte, 1978; Ledru et al., 1989) but also to comparisons between the Variscan belt of Western Europe and the
258 Himalaya-Tibet orogen (Autran and Cogné, 1980; Bard et al., 1980; Burg and Matte, 1978; Dewey and Burke,
259 1973; Mattauer and Etchecopar, 1976; Matte, 1986, 1991). Since its first description, the definition of the LAC
260 has fluctuated and appears to cover a variety of rocks, with emphasis either on the bimodal magmatic association
261 or on the high-pressure metamorphism affecting the mafic and ultramafic rocks (see discussion in Santallier et al.,
262 1988). In addition, the LAC has been recognized at different structural positions and characterized by various
263 metamorphic conditions and ages that led to the addition of a Middle Allochthonous Unit (MAU) in an
264 intermediate position between the UGU and LGU (Berger et al., 2010a, 2010b; Dubuisson et al., 1989; Girardeau
265 et al., 1986; Lotout et al., 2018). The proposed superposition of the UGU (and of the MAU) over the LGU relies
266 on contrasted metamorphic record delineating an inverted metamorphic gradient and locally on the identification
267 of tectonic contacts (Burg et al., 1984; Faure et al., 1979). Based on these characteristics, the main units of the
268 metamorphic nappe stack are, from top to bottom:

269 - The Upper Gneiss Unit (UGU): It is made of garnet/cordierite-bearing diatexites associated with
270 metatexites derived from orthogneisses and paragneisses with relics of granulite facies mineral
271 paragenesis. It has recorded a typical maximum pressure of 10 Kbar for a temperature up to 900 °C
272 retrogressed into amphibolite facies and greenschist facies pointing to decompression and cooling
273 (Audren et al., 1987; Bellot and Roig, 2007; Lardeaux et al., 2001; Schulz et al., 2001; Schulz, 2009) (Fig.
274 4). Geochronological data are consistent with a Devonian to early Carboniferous age for these HP
275 granulite facies migmatites (Do Couto et al., 2016; Duthou et al., 1981, 1994; Lafon, 1986; Schulz, 2014).
276 The Upper Gneiss Unit contains boudins and enclaves of the Leptynite Amphibolite Complex (LAC) that
277 have preserved HT eclogitic relics first discovered in the Haut-Allier and in the Rouergue (Forestier, 1961;
278 Lasnier, 1968; Nicollet, 1977) but then found in most if not all of the LAC enclosed in the UGU (Burg
279 and Matte, 1978; Gardien, 1993; Gardien and Lardeaux, 1991; Mercier et al., 1991). These eclogites have
280 typically recorded PT conditions of c. 15 Kbar for c. 750 °C (Bellot and Roig, 2007; Godard, 1990; Le

281 Breton et al., 1986; Santallier, 1981) but more extreme conditions above 28 Kbar are reported in the
282 Lyonnais (Lardeaux et al., 2001)(Fig. 4). The few available geochronological data for the French Massif
283 Central have served to propose a late Silurian to Devonian age for this HT eclogite facies metamorphism
284 (Do Couto et al., 2016; Ducrot et al., 1983; Paquette et al., 1995; Pin and Lancelot, 1982).

285 - The Middle Allochthonous Unit (MAU): Identified in Limousin, it consists mainly of micaschists
286 associated with an ophiolitic assemblage that is similar to the Leptynite Amphibolite Complex. In contrast
287 to the Upper Gneiss Unit, the LAC of the MAU is marked by relics of LT eclogite facies metamorphism
288 (Berger et al., 2010a, 2010b, Dubuisson et al., 1989, 1989; Girardeau et al., 1986). The maximum pressure
289 recorded by a garnet-kyanite assemblage is 29 Kbar but the temperature did not exceed 660 °C consistent
290 with subduction to 100 km depth (Berger et al., 2010a) (Fig. 4). The pressure peak in Najac is 18 Kbar
291 and the temperature only reached 600 °C (Lotout et al., 2018). These rocks have then been retrogressed
292 into amphibolite facies. Published geochronological data for this LT eclogite facies metamorphism point
293 to a late Silurian age in Central Limousin (Berger et al., 2010a) and middle Devonian in Najac (Lotout et
294 al., 2018).

295 - The Lower Gneiss Unit (LGU): It is made of micaschists, paragneisses and felsic orthogneisses with
296 minor carbonates and mafic rocks. The LGU is affected by greenschist to amphibolite facies
297 metamorphism depicting a Carboniferous Barrovian MP/MT gradient reaching partial melting locally
298 masked by retrogression into greenschist facies (Burg et al., 1984; Burg et al., 1989; Gardien et al., 2011;
299 Gébelin et al., 2009; Nicollet, 1978; Schulz et al., 2001) (Fig. 4).

300 - The Para-Autochthonous Unit (PAU): It is made of micaschists, paragneisses and orthogneisses affected
301 by pervasive Carboniferous greenschist facies metamorphism locally preserving relics of amphibolite
302 facies (Bellot and Roig, 2007) (Fig. 4).

303

304 These high-grade nappes, identified throughout the French Massif Central, are structurally overlain by
305 Metamorphic Upper Units (MUU) with limited lateral extent:

306 - The Thiviers-Payzac Unit: It marks the western edge of the Limousin (Fig. 3). It is made of Cambrian-
307 Ordovician metasedimentary rocks (Bellot and Roig, 2007). The lower part of the Thiviers-Payzac Unit
308 is composed by an assemblage of metagabbros, metadolerites and pyroxene-bearing layered amphibolites
309 (Bellot and Roig, 2007; Santallier, 1981) suspected to represent an ophiolitic mélange.

310 - The Génis Unit: It overlies the Thiviers-Payzac Unit (Fig. 3). It is composed of unmetamorphosed gabbro,
311 dolerite, basalt and cherts (Cabanis et al., 1983; Maillet et al., 1984)-associated with Ordovician-Devonian

312 sericite micaschist and middle Devonian limestones (Guillot and Doubinger, 1971; Guillot and Lefevre,
313 1975). This assemblage has been interpreted to represent a middle Devonian ophiolitic mélange (Ledru
314 et al., 1989) or a late Devonian – early Carboniferous olistostrome reworking a Devonian ophiolite (Faure
315 et al., 2009a).

- 316 - The Somme Unit: It is exposed south of the Morvan (Fig. 3). It is characterized by middle to late Devonian
317 unmetamorphosed weakly deformed sedimentary and volcanic rocks (Delfour et al., 1989). Marine
318 carbonates of Givetian and Frasnian age alternate with calc-alkaline volcanics and volcanoclastics
319 associated with massive sulphide deposits and are capped by Famennian clastic sediments (Delfour et al.,
320 1989). This association is consistent with the construction of a magmatic arc along a convergent active
321 margin (Faure et al., 2008).
- 322 - The Brévenne Unit. It is located south of the Morvan and north of the Monts du Lyonnais (Fig. 3). It
323 comprises ultramafics, gabbros, pillow basalts, siliceous sedimentary rocks and massive sulphide deposits
324 attributed to a late Devonian ophiolitic sequence (Bébié, 1971; Bitri et al., 1999; Leloix et al., 1999;
325 Milési and Lescuyer, n.d.; Pin, 1990; Pin and Paquette, 2002; Sider and Ohnenstetter, 1986). Volcanics
326 display contrasting low-K calc-alkaline to tholeiitic signatures, suggesting an emplacement in an
327 immature back-arc basin (Bébié, 1971; Pin, 1990; Pin and Lancelot, 1982; Pin and Paquette, 1997; Sider
328 and Ohnenstetter, 1986). These magmatic rocks have been dated at 366 ± 5 Ma and 358 ± 1 Ma by U-Pb on
329 zircon (Pin and Paquette, 1997).

330

331 ***Protoliths age for the high-grade rocks, basement of the Devonian to Carboniferous volcanic and sedimentary***
332 ***units***
333

334 The first proposed ages for the different lithological units exposed in the French Massif Central relied on relative
335 chronology based on stratigraphy, biostratigraphy and cross-cutting relationships (Jung, 1953; Roques, 1971). The
336 intensity of metamorphism and deformation affecting rocks forming the UGU, MAU, and LGU precludes the
337 identification of fossils in high-grade metasedimentary rocks and the recognition of initial magmatic-sedimentary
338 contacts. Thus, protoliths age determination relying mostly on analogies with stratigraphic ages determined in
339 other regions are subject to caution. Recent age determinations based on radiometric dating of inherited zircon
340 grains (distinguished from Variscan metamorphic zircon) provide (i) a maximum age (the youngest age obtained
341 on inherited grains) for the deposition of the sediments protoliths of paragneisses, and (ii) a crystallization age for
342 magmatic rocks, protoliths of orthogneisses, and/or amphibolites and other mafic metaplutonics. Ages spreading
343 from the late Neoproterozoic (Ediacarian) to the early Paleozoic (Cambrian to Ordovician) have been attributed to

344 most of the metasedimentary sequences (Chantraine et al., 2003; Franke, 2000; Linnemann et al., 2007). Protoliths
345 ages of metamorphic rocks (Chelle-Michou et al., 2017; Couzinié et al., 2017, 2019; Duthou et al., 1994; Lotout
346 et al., 2018; Melleton et al., 2010; Pin and Duthou, 1990; R’Kha Chaham et al., 1990)(Fig. 5) indicate (i) an
347 Ediacarian to Ordovician age for metasediments deposited along the former margin of the Gondwana continent,
348 (ii) Ediacarian, Cambrian and Ordovician ages for orthogneisses, and (iii) a Cambrian to Ordovician age for the
349 mafic and ultramafic rocks. According to these data, the only identified Proterozoic basement in the French Massif
350 Central corresponds to the paragneisses and orthogneisses with Ediacarian protoliths.

351

352 *Migmatites and granulites*

353

354 In addition to the HP granulite facies migmatites that are part of the UGU, MP and LP migmatites, developed to
355 the expense of late Neoproterozoic to early Paleozoic paragneisses and orthogneisses, are exposed at the lowest
356 structural level of the nappe pile in the Limousin, Velay and Montagne Noire (Barbey et al., 2015; Downes et al.,
357 1997; Gébelin et al., 2009; Ledru et al., 2001; Villaros et al., 2018; Williamson et al., 1996). In the Limousin, PT
358 conditions of 850-750 °C and 5-6 Kbar have been estimated for the cordierite-bearing migmatitic gneisses and
359 associated lenses of leucosomes of the Millevaches massif in the Limousin dated at c. 315 Ma (Gébelin et al.,
360 2009). In the Montagne Noire, migmatites coring the Caroux dome have recorded P-T conditions of 6 Kbar and
361 720 °C (Rabin et al., 2015). They contain magmatic zircon with U-Pb ages spreading from c. 330 to c. 300 Ma
362 (Faure et al., 2014; Franke et al., 2011; Roger et al., 2015). In the Velay dome, migmatites display contrasting P-
363 T conditions and ages as a function of their structural position. Along the dome’s margin, migmatites have recorded
364 partial melting with biotite remaining stable at a pressure over 5 Kbar for a temperature over 750 °C (Montel et
365 al., 1992a). These migmatites contain monazite that yield microprobe U-Pb ages ranging from c. 329 to 314 Ma
366 (Be Mezeme et al. 2006; Cocherie et al. 2005; Mougeot et al. 1997). In contrast, migmatites coring the Velay dome
367 have recorded fluid-absent biotite melting in the cordierite stability field with P-T estimates of 2-5 Kbar and 760-
368 850 °C (Barbey et al., 1999, 2015; Montel et al., 1992b; Villaros et al., 2018). These migmatites display a Rb-Sr
369 whole rock age of 298 ± 8 Ma (Rb - Sr whole-rock, Caen-Vachette Vachette et al. 1982) and contain monazite
370 dated at 301 ± 5 Ma by U-Pb (Mougeot et al. 1997).

371

372 The nature of the lower crust underlying these migmatites is documented by xenoliths included in late Variscan
373 plutonic rocks and in Cenozoic basaltic lavas. Biotite-sillimanite enclaves incorporated in diorite intrusive in the
374 southern margin of the Velay dome have recorded P-T conditions of 8-10 Kbar for 700-800 °C (Montel, 1985).

375 The main mineral paragenesis of felsic and mafic granulites xenoliths in Cenozoic lavas indicate a pressure of 8-
376 10 Kbar for a temperature of 700-800 °C followed by isothermal decompression at 5-6 Kbar (Downes and
377 Leyreloup, 1986; Leyreloup, 1974). A few metaigneous xenoliths have preserved relics pointing to a pressure as
378 high as 14 Kbar for a temperature of c. 900 °C. These granulites contain zircon grains that yield U-Pb ages ranging
379 from 320 to 280 Ma (Downes et al., 1991). The geochemical signatures of the granulites with a metasedimentary
380 protolith indicate a refractory or residual character while the mafic and felsic metaigneous granulites display
381 characteristics of a calc-alkaline liquid and of a cumulate, respectively (Downes et al., 1990; Dupuy et al., 1979;
382 Vielzeuf and Vidal, 2012). The representation of the deep part of the cross sections (Fig. 8) is in part based on
383 these characteristics.

384

385 *Late Devonian to Carboniferous plutonic rocks*

386

387 The c. 70 to 80 Ma-long magmatic activity recorded by plutonic and minor volcanic rocks of the French Massif
388 Central is characterized by an extreme variety of petrological types and geochemical signatures. In this section,
389 we describe these petrologic and geochemical characteristics and discuss their significance integrating their spatial
390 distribution and their ages of emplacement. The petrology and geochemistry of granitoids, as described in the
391 1/1'000'000 geological map of France (Chantraine et al., 2003) is following the classification by Barbarin (1999).
392 Four types are distinguished (Fig. 6):

393

- 394 - Calc-alkaline granitoids equivalent to the amphibole-rich calc-alkaline granitoids (ACG) of Barbarin
395 (1999) include tonalites, granodiorites and granites. In addition to amphibole, they may contain pyroxene,
396 and frequently include enclaves and small volumes of gabbro to diorites (i.e. more mafic terms of the
397 same serie). They are essentially similar to arc granitoids typically attributed to fractional crystallization
398 of an enriched mafic magma.
- 399 - Peraluminous granites and leucogranites correspond to muscovite or muscovite+biotite bearing granites
400 sensu-stricto equivalent to the muscovite-bearing peraluminous granitoids (MPG) of Barbarin (1999).
401 They are attributed to relatively cold (<850°C, water present- or muscovite breakdown) melting of
402 metasediments (Gardien et al., 1995; Villaros et al., 2018) and might represent the first melt extracted
403 from the partially molten source at the onset of partial melting.
- 404 - Peraluminous granites to granodiorites, corresponding to the cordierite-bearing peraluminous granitoids
405 (CPG) of Barbarin (1999). They probably relate to relatively hot ($\geq 850^{\circ}\text{C}$, biotite breakdown) melting of
406 a continental felsic source (ortho or paragneisses) (Barbey et al., 1999; Gardien et al., 1995; Villaros et

407 al., 2018). They might represent a partially molten source with a high-melt fraction (i.e. diatexites)
408 implying inefficient melt and/or magma extraction but possibly also some solid settling.
409 - High-K sub-alkaline granitoids, i.e. K-feldspar porphyritic calc-alkaline granitoids (KCG) of Barbarin
410 (1999). They are porphyritic granites to granodiorites, commonly amphibole-bearing, and they typically
411 contain abundant accessory minerals such as apatite and titanite. They contain micro-granular mafic
412 enclaves, and are associated with intermediate plutonic rocks (diorites, to tonalites, to monzodiorites) of
413 similar, “vaugneritic” (see below) composition to which they are probably petrogenetically related
414 (Moyen et al., 2017).

415
416 In addition, granites and migmatites are associated with mafic but potassic plutonic rocks locally known as
417 “vaugnerites” (Michon, 1987; Sabatier, 1991). Vaugnerites range from diorites to syenites and consist of
418 amphibole, biotite, clinopyroxene, plagioclase, rare orthopyroxene, interstitial K-feldspar and quartz (Sabatier,
419 1991). Vaugnerites are K-, LILE- and LREE-rich mafic to intermediate rocks, pointing to an origin by partial
420 melting of a mantle source enriched by the addition of crustal components, probably during earlier subduction
421 (Couzinié et al., 2013, 2016; Rapp et al., 2010). They form the most mafic components of the KCG suites.
422 Interestingly, they are undistinguishable from CPG and MPG from an isotopic point of view (Sr, Nd or Hf)
423 (Couzinié et al., 2016; Moyen et al., 2017; Williamson et al., 1992).

424
425 The study of vaugnerites and their counterparts in other orogenic settings worldwide, indicate that their
426 characteristics unlikely result from the crustal contamination of basaltic magma on their way to the surface and are
427 rather primarily inherited from a mantle source enriched by crustal components (Campbell et al., 2014; Couzinié
428 et al., 2016; Laurent et al., 2011, 2014; Prelević et al., 2012; Williams, 2004). It should be mentioned that
429 vaugnerites are similar to the “durbachites” described in other parts of the Variscan belt (Sabatier, 1991; von
430 Raumer et al., 2014). Such rock types are present in most if not all orogenic settings elsewhere in the world where
431 they are called “appinites”, “redwitzite”, “high Sr-Ba granitoids” (Fowler et al., 2001) or “sanukitoids” in an
432 Archean context (Heilimo et al., 2010; Martin et al., 2005). In the FMC, the isotopic similarity between vaugnerites
433 and crust-derived granites shows that the crustal component was derived from the local crust, probably during
434 (continental) subduction shortly prior to melting (Couzinié et al., 2016; Moyen et al., 2017). A similar model is
435 proposed for the c. 345 Ma old KCG granitoids (the Blatna suite) of the Bohemian Massif (Janoušek et al., 2004;
436 Janousek and Holub, 1997), suggesting that KCG may derive from similar petrogenetic processes as vaugnerites,
437 and typically represent their differentiated products. However, this is not so clear for the FMC where KCG may

438 also derive from interactions between vaugnerites and melts derived from the local crust, such as CPG and MPG
439 (Laurent et al., 2017; Moyen et al., 2017; Solgadi et al., 2007). In either case, KCG are genetically linked to the
440 vaugnerites so they are classified together with them in the following as “mantle-derived” granitoids.

441

442 *Carboniferous volcanic and sedimentary deposits*

443

444 In the northern part of the French Massif Central, crystalline rocks are locally capped by middle Carboniferous
445 (Visean: c. 347-325 Ma) volcanic and marine deposits, as exemplified in the Sioule, Morvan and Brévenne regions,
446 implying that they were exhumed and below sea-level at this time (Bertaux et al., 1993; Franke, 2014). In the
447 southern part of the French Massif Central, Devonian to mid-Carboniferous (Visean) carbonates and turbidites are
448 unconformably deposited on plutonic rocks and Ediacarian to Ordovician orthogneisses and paragneisses, in an
449 underfilled foreland basin at the front of a propagating, low-grade fold-and-thrust system (Franke and Engel, 1986;
450 Souquet et al., 2003). Namurian (c. 330-325 Ma) olistoliths and probably Westphalian (c. 325-304 Ma) turbidites
451 and coarse conglomerate deposits attest for the erosion of a growing mountain belt to the north (Engel et al., 1978,
452 1981; Engel, 1984).

453

454 Clastic sediments associated with minor volcanics of late Carboniferous (Stephanian) and Permian ages are
455 unconformably deposited on top of the crystalline rocks in extensional basins associated with strike-slip shear
456 zones marking the waning stages of the Variscan orogeny (Becq-Giraudon, 1993; Becq-Giraudon et al., 1996;
457 Ménard and Molnar, 1988; Van Den Driessche and Brun, 1992). Presence of coal in the Stephanian basins attests
458 for a high-geothermal gradient (Copard et al., 2000), which could be attributed to the juxtaposition of the sediments
459 to high-grade rocks freshly exhumed along low-angle detachments. Permian basins are typically wider than
460 Stephanian ones suggesting progressive aplanation of the Variscan topography at the end of the Carboniferous.

461

462 In summary, the superposition of the UGU over the MAU, LGU and PAU define an inverted metamorphic gradient
463 with HP granulite facies migmatites overlying amphibolite facies paragneisses and orthogneisses with locally
464 preserved LT eclogites. The structural, petrological and geochronological record of these nappes document a
465 diachronous history of burial, exhumation and emplacement spreading from the late Silurian to the Devonian. The
466 top of the nappe pile is locally marked by Metamorphic Upper Units (MUU). The lowest structural level is
467 composed of MP to LP migmatites exposed in the Limousin, and in the Velay and Montagne Noire domes. The
468 nappe pile is dissected by strike-slip shear zones and low-angle detachments. It is intruded by plutonic rocks with
469 ages ranging from late Devonian to late Carboniferous-Permian. These crystalline rocks are capped by volcanic

470 and sedimentary rocks deposited in intramontane and foreland basins with ages also ranging from late Devonian
471 to Permian. The detailed structural relationships between these different lithological units and the timing of
472 geological events is further presented in the next section.

473

474 **2.3. Architecture and P-T-t record of nappes of the western and eastern French** 475 **Massif Central**

476

477 As stated above, the identification of the LAC as a suture led to the revival, after the pioneer proposition of Demay
478 (1948), of the nappe concept in the French Massif Central and several models have been proposed ever since. The
479 early tectonic model (Burg and Matte, 1978; Matte, 1986) highlights three distinct nappes cored by the migmatites
480 of the UGU; namely from north to south, the Sioule, the Haut Allier – Marvejols, and the Rouergue nappes (Fig.
481 7). In this model each outcropping zone of the UGU and associated LAC corresponds to a locally rooted nappe
482 that, in turn delineates a suture and thus a former oceanic basin. In contrast, subsequent models (Faure et al., 2009a;
483 Lardeaux, 2014; Matte, 1991, 2001) propose that these three nappes form only one with the LAC representing a
484 single ocean rooted beneath the Paris Basin. Consequently, the discontinuous outcrops of the UGU with enclaves
485 of LAC are interpreted as klippe.

486

487 The high-grade nappes are characterized by a penetrative composite foliation resulting from superimposed
488 structures and metamorphic parageneses that is typically parallel to the tectonic contacts. This foliation is
489 dominantly shallow dipping (Burg and Matte, 1978; Faure et al., 2009a; Matte, 1986) but is locally steeply dipping
490 such as in the Livradois or in the Monts du Lyonnais (Feybesse et al., 1988; Gardien et al., 1990, 2011; Lardeaux
491 and Dufour, 1987). Away from strike slip shear zones, the lineation associated with this composite foliation is
492 dominantly E-W to WNW-ESE trending in the western part of the French Massif Central and in the Sioule region
493 but is dominantly N-S to NNE-SSW trending in the eastern part (Faure et al., 2009a). Moreover, this foliation is
494 in place affected by regional upright folding such as in the Limousin (Burg and Matte, 1978; Girardeau et al., 1986;
495 Matte, 1986). The structure of the nappe pile is blurred by numerous granitic plutons and original contacts are
496 reworked by thrusts, strike-slip shear zones, low-angle detachments and high-angle normal faults. This complex
497 structural record and the scarcity of outcrops impedes the identification of the original tectonic contacts between
498 the nappes in most places. Nevertheless, in order to discuss the tectonic evolution of potentially distinct nappes,
499 in the following sections, we review available data regarding the structural position and P-T-t record of the

500 lithological-tectonic units presented above distinguishing the Western and Eastern parts of the French Massif
501 Central separated by the Sillon Houiller Fault (Figs. 8, 9, 10).

502

503 *Western French Massif Central (W-FMC)*
504

505 In the northern part of the W-FMC, the Aigurande region is exposing metamorphic rocks unconformably overlain
506 by Mesozoic sediments of the Paris Basin to the north and is delimited by the La Marche shear zone to the south
507 (Fig. 8 cross section AA'). Metamorphic rocks present a polyphased structural and metamorphic history associated
508 with an inverted metamorphic gradient characterized by the superposition, from top to bottom, of the UGU, the
509 LGU and PAU (Faure et al., 1990; Quenardel and Rolin, 1984). At the top of the nappe pile, the UGU is dominated
510 by diatexites and metatexitic orthogneisses and paragneisses with rare quartzites. These rocks display a dominant
511 garnet-sillimanite-cordierite mineral paragenesis with relics of kyanite that attest for HP partial melting followed
512 by retrogression during decompression. The amphibolite facies foliation of these migmatites is associated with
513 top-to-the SE sense of shear criteria considered to record nappe emplacement (Faure et al., 1990). The boundary
514 between the UGU and the LGU is marked by boudins of eclogitic amphibolites and of ultramafics attributed to the
515 LAC. Amphibolites that are part of the LAC, yield $^{40}\text{Ar}/^{39}\text{Ar}$ dates on amphibole at 389 ± 8 Ma interpreted as the
516 age of amphibolite facies metamorphism (Boutin and Montigny, 1993). A mylonitic shear zone underlines the
517 contact between the migmatitic units of the LGU and micaschists attributed to the PAU (Faure et al., 1990). This
518 contact was first interpreted as a thrust responsible for burial of the PAU beneath the LGU (Quenardel and Rolin,
519 1984). In contrast, retrogression of the garnet-biotite dominant foliation of the micaschists associated with top-to-
520 the NE kinematic criteria has been reinterpreted as reflecting exhumation of the PAU during a period of regional
521 extension estimated at 325 - 312 Ma based on syntectonic leucogranites emplacement (Faure et al., 1990). It is
522 noteworthy that these micaschists of the PAU contain relics of kyanite and staurolite attesting for an undated
523 MP/MT amphibolite facies metamorphism before retrogression into greenschist facies.

524

525 To the north of the FMC, the crystalline basement beneath the Paris Basin has been sampled in the Couy deep
526 borehole down to 3500 m (Fig. 1). Granulite facies migmatites of the UGU are associated with metabasites
527 attributed to the LAC with a Cambrian-Ordovician protolith as constrained by a Sm-Nd isochron of 494 ± 17 Ma
528 and a U-Pb zircon date of 497 ± 13 Ma (Pagel et al., 1992). These rocks display a NE-SW trending foliation steeply
529 dipping to the SE. The granulite facies mineral paragenesis yield a pressure ranging from 15 to 9 Kbar and a
530 temperature from 900 to 650 °C. Retrogression into the amphibolite facies is recorded at c. 6 Kbar for c. 600 °C
531 (Ballèvre and Balé, 1992; Burg et al., 1989). Amphibolites yield an Rb-Sr isochron of 387 ± 2 Ma interpreted as

532 dating high-grade metamorphism. $^{40}\text{Ar}/^{39}\text{Ar}$ ages on amphibole and biotite from granulite facies amphibolites and
533 orthogneisses, respectively range from c. 385 Ma to c. 379 Ma and point to rapid cooling below 300 °C before the
534 end of the Devonian (Costa and Maluski, 1988). Accordingly, the P-T-t record of the UGU sampled in the Couy
535 deep borehole is similar to the one of the UGU exposed in the Aigurande region and these rocks are attributed to
536 the same nappe that will be designated as the northern nappe in the following.

537
538 South of the Aigurande region, the northern Limousin region exposes a slightly different nappe package. The UGU
539 is mainly made of migmatitic paragneisses with ubiquitous relics of HP metamorphism expressed as eclogites and
540 numerous garnet amphibolite boudins (Le Breton et al., 1986). Below, the LGU exposed in the core of the Thaurion
541 and Meuzac antiforms (Fig. 8 cross section AA') is dominated by amphibolite facies orthogneisses with some
542 paragneisses. In addition to the high-grade units recognized in the Aigurande region, several authors have
543 identified a Middle Allochthonous Unit (MAU) stacked in between the UGU and LGU (Berger et al., 2010a, 2010b;
544 Dubuisson et al., 1989; Girardeau et al., 1986). The UGU contains eclogite facies metabasites attributed to the
545 LAC yielding U-Pb zircon ages pointing to a crystallization of their protolith between c. 489 and c. 475 Ma. The
546 eclogitic UHP event is dated at 412 ± 10 Ma followed by a resetting potentially linked to partial melting and
547 retrogression into the granulite facies at 382 ± 7 Ma (Berger et al., 2010a), which is also consistent with previous
548 whole rock Rb-Sr isochrons from c. 385 to c. 375 Ma (Duthou, 1978; Duthou et al., 1994), U-Pb on zircon at
549 383 ± 5 Ma (Lafon, 1986) and U-Th-Pb on monazite between c. 378 and c. 374 Ma (Faure et al., 2008). The
550 relationship between this nappe pile and the one exposed in the Aigurande region is not clearly identified but the
551 differences displayed by their cooling histories points to distinct exhumation histories. In the following, the nappe
552 exposed in the northern Limousin will be designated as the Central nappe.

553
554 In the southern Limousin the nappe pile is deformed in a serie of upright folds designated as the Uzerche synform
555 and the Tulle antiform (Ledru et al., 1989)(Fig. 8 cross section AA'). The UGU is dominated by granulite facies
556 migmatitic paragneisses with eclogitic mafic boudins yielding peak metamorphic conditions at c. 15 Kbar and c.
557 750 °C (Bellot and Roig, 2007; Santallier, 1981). In a lower structural position, migmatitic paragneiss and
558 orthogneiss that contain boudins/enclaves of eclogites and garnet-spinel peridotites with peak P-T conditions at c.
559 15 Kbar and c. 700 °C similar to the ones of the UGU (Bellot and Roig, 2007; Ledru et al., 1989; Santallier, 1981).
560 These eclogitic boudins have been first attributed to the LGU but could be part of the MAU according to their
561 structural position and P-T record. Structurally below these rocks, migmatitic paragneisses display a syn-
562 migmatitic foliation underlined by cordierite-sillimanite-bearing leucosomes that document a retrograde P-T path

563 from c. 9.5 Kbar at c. 850 °C to c. 6 Kbar at c. 600 °C and locally to c. 3.5 Kbar at c. 550 °C (Bellot and Roig,
564 2007). These migmatites yield a U-Pb age on zircon at 382 ± 5 Ma interpreted as the age of partial melting (Lafon,
565 1986) and a variety of $^{40}\text{Ar}/^{39}\text{Ar}$ ages on micas as well as U-Th-Pb ages on monazite spreading from c. 350 Ma to
566 c. 315 Ma that might reflect progressive exhumation and cooling, or partial resetting owing to recrystallization,
567 during the Carboniferous (Costa, 1992; Gebelin et al., 2004; Melleton et al., 2009). The high-grade nappes are
568 overlain by the Thiviers-Payzac Unit and by the Génis Unit (Bellot and Roig, 2007; Guillot and Doubinger, 1971;
569 Guillot and Lefevre, 1975; Santallier, 1981) that are affected by a prograde Barrovian metamorphic gradient with
570 peak conditions at c. 9 Kbar for c. 750 °C at the lowest structural level. The Thiviers-Payzac Unit is intruded by
571 pre-tectonic calc-alkaline dolerite dykes dated at 363 ± 10 Ma by K-Ar on whole rock (Bellot and Roig, 2007). The
572 presence of high-grade rocks of the UGU sandwiched in between lower-grade rocks is interpreted to correspond
573 to vertical extrusion of the high-pressure UGU into an orogenic wedge affected by Barrovian metamorphism
574 (Bellot and Roig, 2007), as envisioned in models of Chemenda et al. (1996) or Escher and Beaumont (1997).
575 According to these data, the South Limousin UGU is characterized by a younger cooling history than the North
576 Limousin one, which is used to define what will be referred as the southern nappe in the following.

577

578 The oldest Variscan plutonic rocks identified in the Western part of the French Massif Central are late Devonian
579 and display a variety of petrological and geochemical signatures. Small plutons emplaced into the UGU (ACG
580 type of Barbarin 1999), with a composition ranging from gabbro to granodiorite and signatures from calc-alkaline
581 to tholeiitic, define a broadly linear trend referred to as the “Limousin tonalite line” (Cuney et al., 1990, 1993;
582 Peiffer, 1986). These rocks first yielded TIMS U-Pb zircon ages of 379 ± 19 Ma and 355 ± 2 Ma (Bernard-Griffiths
583 et al., 1985) and have since provided more precise ages of 365 ± 3 Ma and 360 ± 1 Ma by the same method (Pin and
584 Paquette, 2002). In contrast, the contemporaneous Guéret pluton (Turpin et al., 1990) is a cordierite-bearing
585 peraluminous granite (CPG in the nomenclature of Barbarin, 1999) dated in the late Devonian (Berthier et al.,
586 1979). It forms a c. 1 km thick laccolith overlying the cordierite-bearing migmatitic gneisses of the UGU (Dupis
587 et al., 1990; Gébelin et al., 2006; Lameyre et al., 1988). These plutonic rocks are cross-cut by a system of E-W to
588 NW-SE trending dextral shear zones including the La Marche, Courtine and Pradines shear zones that started their
589 activity at about 350 Ma as attested by $^{40}\text{Ar}/^{39}\text{Ar}$ on syntectonic biotite in the Aigurande plateau (Gébelin et al.,
590 2007). These shear zones control the syntectonic emplacement of CPG and MPG plutons from 345 to 310 Ma
591 (Alexandrov et al., 2001; Gébelin et al., 2007, 2009; Lafon and Respaut, 1988; Lerouge and Quenardel, 1988;
592 Rolin et al., 2009, 2014), bounded at their roof by detachment zones (Faure and Pons, 1991; Gébelin et al., 2007).

593 Leucogranites are interpreted to be generated by partial melting of a metasedimentary middle crust (Cuney et al.,
594 1990; Moyen et al., 2017; Williamson et al., 1996). This is consistent with their structural position relative to their
595 host rocks, as exemplified by the Millevaches laccolith rooted into cordierite-bearing migmatitic paragneisses that
596 have been affected by partial melting under MP/MT amphibolite facies conditions (6 Kbar for 850 °C) as attested
597 by leucosomes localized in strike-slip shear bands (Gébelin, 2004; Gébelin et al., 2006, 2009). The minimum age
598 of this high-grade metamorphism and partial melting have been dated at 315 ± 4 Ma and 316 ± 2 Ma, coeval with
599 the syntectonic emplacement of leucogranites in the Pradines dextral strike-slip shear zone at 313 ± 4 Ma (Gébelin
600 et al., 2009). The dextral strike-slip shear zones are cross-cut by high-angle normal faults and low-angle
601 detachments such as the NE-SW trending Nantiat and Bussière shear zones and the N-S trending Argentat shear
602 zone (Fig. 3)(Gébelin et al., 2007, 2009). The footwall of these detachment zones represented sites of strong
603 (meteoric) fluid-rock-deformation interactions during the late Carboniferous (Dusséaux, 2019; Dusséaux et al.,
604 2019). Exhumation along these low-angle mylonite zones is constrained to be middle (Visean) to late
605 Carboniferous (Stephanian) in age, by argon thermochronology (Alexandrov et al., 2000; Gébelin, 2004; Gébelin
606 et al., 2007; Roig et al., 2002; Rolin et al., 2014). The activity of these shallow dipping detachments and strike-
607 slip shear zones, which are part of the Sillon Houiller Fault, controlled the deposition of late Carboniferous coal-
608 bearing sediments in small extensional and pull-apart basins (Feybesse, 1981; Thiéry et al., 2009). The onset of
609 deposition in these basins during the Visean is confirmed by a fireclay dated at 332 ± 4 Ma by U-Pb TIMS on zircon
610 in northern Limousin (Bruguier et al., 1998). The Permian clastic sedimentary deposits of the Brive basin
611 unconformably overlie these late Carboniferous deposits and mark the end of the Variscan tectonic activity in this
612 region.

613
614 Although scarce, available geophysical data for the W-FMC provide some constraints on the deep crustal structure.
615 Gravity data indicate that most plutons are laccoliths with an average thickness of about 1 km but that can locally
616 reach up to 3 km (Gébelin et al., 2006; Joly et al., 2008, 2009). As a complement, seismic data allow to identify
617 the prolongation of surface structures at depth (Bitri et al., 1999). In the upper crust, the main feature is that most
618 reflectors appear to match the projection of the dominantly shallow-dipping high-grade fabric parallel to
619 lithological-tectonic contacts identified at the surface. These reflectors are only crosscut and offset by high-angle
620 faults and low-angle detachments. For example, high-angle faults separating the North and South Limousin and
621 affecting high-grade rocks coring the Meuzac antiform, are offsetting reflectors marking the contacts between the
622 UGU, MAU, LGU and PAU and are rooted into a high reflectivity zone at 10 km depth. Similarly, the Argentat
623 shear zone corresponds to a several km thick zone of reflectors shallowly dipping to the West rooting into a

624 reflective zone at about 10 km depth. Accordingly, the Argentat shear zone might be interpreted as the breakaway
625 zone of a low-angle detachment rooted in the brittle-ductile transition. These high reflectivity zones are overlying
626 a c. 10 km thick seismically transparent middle crustal zone with a relative low density that has been interpreted
627 to be composed of granitic material (Bitri et al., 1999). Alternatively, this middle crust, coring low amplitude (few
628 km) and long wavelength (tens of km) dome-shaped structures, could be composed by migmatites, as it has been
629 proposed for similar structures detected beneath low-angle detachments in the South Armorican Massif (Bitri et
630 al., 2010). Beneath this transparent middle crustal zone, the lower crust is typically marked by its high reflectivity
631 from c. 20 km down to the Moho at c. 30 km depth (Bitri et al., 1999). These characteristics are used to constrain
632 the deep part of the cross sections (Fig. 8) beyond information provided by surface outcrops.

633

634 *Eastern French Massif Central (E-FMC)*

635

636 The continuity of the nappes from the W-FMC to the E-FMC across the Sillon Houiller Fault is not easily
637 established. Nevertheless, as for the W-FMC, the P-T-t record of high-grade rocks of the E-FMC points to the
638 diachronous emplacement of several distinct nappes.

639

640 In the northern part of the E-FMC, the position of the late Devonian Brévenne back-arc, to the south of the Morvan
641 arc represented by the late Devonian Somme Unit, has been used to infer a southward subduction of the Rheic
642 Ocean along a continental active margin (Faure et al., 1997, 2008). Sparse outcrops of retrogressed eclogites,
643 serpentinised peridotites and amphibolites affected by HP metamorphism are characteristic of the UGU (Gardien
644 et al., 1988; Godard, 1990). The timing of exhumation of these high-grade rocks and their structural relationships
645 with the Devonian volcanic-sedimentary sequences are ill-defined. However, it has been proposed that they were
646 already exhumed before the middle Devonian at the time of formation of the Morvan arc and Brévenne back-arc
647 (Faure et al., 1997, 2008). In that case, the UGU exposed in the Morvan region might correspond to the northern
648 nappe described in the W-FMC. Because of these uncertainties, this part of the French Massif Central is not
649 represented on cross sections of figure 8.

650

651 In the Sioule area (Fig. 8 cross section BB'), the Variscan basement shows a dominant shallow-dipping composite
652 foliation deformed in a broad antiform cored by granitic plutons and displaying an inverted metamorphic gradient
653 (Faure et al., 1993, 2002). The top of the nappe pile is made of cordierite-bearing diatexites and migmatitic
654 orthogneisses and paragneisses that have recorded isothermal decompression from 12-13 Kbar to 2-3 Kbar at 650-
655 700 °C. Both lithologies display a composite foliation bearing a NE-SW trending lineation (Audren et al., 1987;

656 Schulz et al., 2001; Schulz, 2009). Serpentinite boudins and granulitic relics allow to assign these rocks to the
657 UGU (Ravier and Chenevoy, 1979). Metamorphic monazite with a U-Th-Pb EPMA age at 416 ± 15 Ma is attributed
658 to HP metamorphism (Do Couto et al., 2016) but retrogression under amphibolite facies has not been dated. The
659 contact with the lower-grade underlying micaschists attributed to the PAU has first been interpreted as a thrust
660 (Burg and Matte, 1978; Ledru et al., 1989) but has been then attributed to an extensional detachment reflecting
661 exhumation of the PAU during Visean regional extension dated at 337-336 Ma by Ar thermochronology on mica
662 and amphibole of syntectonic granites (Faure et al., 1993, 2002). Despite uncertainties on the timing of exhumation
663 of the UGU in the Morvan and Sioule regions, we propose to consider that they are part of the same northern nappe
664 exhumed, at least partly, during the late Devonian as previously proposed by Faure et al. (Faure et al., 1997, 2008).
665 The southern boundary of the Sioule-Morvan high-grade nappe is marked by a dextral strike-slip corridor
666 (Hermitage shear zone) crossing the Forez and Brévenne regions and localizing the emplacement of syn-tectonic
667 MPG plutons dated from 330 to 320 Ma (U-Pb on zircon, (Laurent et al., 2017). These high-grade metamorphic
668 and plutonic rocks are capped by Visean undeformed volcanics, volcanoclastics and granophyres represented by
669 the “tufs anthracifères” series dated at 336 ± 5 Ma by a Rb-Sr isochron (Carrat and Zimmermann, 1984; Delfour et
670 al., 1989; Faure et al., 2002; Leloix et al., 1999; Sider and Ohnenstetter, 1986). A similar age of 332 ± 2 Ma has
671 been obtained by U-Pb TIMS on zircon from a rhyolite sampled in the Decazeville basin (Bruguier et al., 1998).
672 These Visean volcanic rocks are locally associated with marine deposits, which has been used to propose that the
673 high-grade rocks of the nappe pile were exhumed but remained below sea-level at this time (Franke, 2014).
674
675 South of the Hermitage shear zone, several fragments of the UGU, composed of migmatitic paragneisses and
676 orthogneisses grading from metatexites to diatexites, are exposed in the Combrailles, Cézallier, Artense, Livradois,
677 Truyère, Haut-Allier, Lyonnais and Vivarais regions (Feybesse et al., 1988; Gardien, 1993; Gardien et al., 2011;
678 Gardien and Lardeaux, 1991; Lardeaux and Dufour, 1987; Mercier et al., 1991)(Fig. 8 cross section BB', CC',
679 DD'). We propose here that these litho-tectonic units are part of the central nappe. The migmatitic gneisses of the
680 UGU yield whole rock Rb-Sr isochrons ranging from 385 to 375 Ma in the Lyonnais (Duthou et al., 1981, 1994)
681 and a monazite age of 360 ± 4 Ma by U-Th-Pb EMPA in the Livradois (Gardien et al., 2011; Vanderhaeghe et al.,
682 2013). These ages are tentatively interpreted to record the transition from an early stage of HP granulite facies (at
683 least 10 Kbar for c. 800 °C) followed by decompression to 6 Kbar. In the northern root zone of this nappe, exposed
684 in the Lyonnais and Livradois, the NE-SW trending regional foliation of the UGU's migmatites is steeply dipping
685 to the north (Feybesse et al., 1988; Gardien et al., 1990, 2011; Lardeaux and Dufour, 1987)(Fig. 8 cross sections
686 CC', DD'). North of the Livradois, these migmatites display a penetrative C/S fabric consistent with a top to the

687 south sense of shear (Gardien et al., 2011; Koné, 1985; Vanderhaeghe et al., 2013). To the north of the Lyonnais,
688 the late Devonian volcanic-sedimentary series of the Brévenne unit are characterized by upright folds with an
689 NNE-SSW trending axial planar schistosity under greenschist facies metamorphism (Fig. 8 cross section DD').
690 The contact between the Brévenne Unit and the UGU of the Lyonnais is marked by transposition of previous
691 structures into NE-SW trending shallow-dipping shear zone (Feybesse et al., 1988), also delineated by a
692 syntectonic granite displaying a C/S fabric consistent with a top to the NW sense of shear (Feybesse et al., 1988;
693 Leloix et al., 1999). Deformation of this granite is dated at 339-337 Ma by $^{40}\text{Ar}/^{39}\text{Ar}$ on recrystallized muscovite
694 (Faure et al., 2002), which is consistent with both Rb-Sr whole rock isochrons obtained by Gay et al. (1981) on
695 the syntectonic granite and by Vialette (1973) on genetically linked hypovolcanics (Faure et al., 2002; Leloix et
696 al., 1999), giving ages at 339 ± 8 and 336 ± 5 Ma respectively. These data suggest that at least part of the exhumation
697 of the UGU in this region occurred during the early Carboniferous and was associated with top to the NW shearing.
698 In the Livradois (Fig. 8 cross section CC'), the southern part of the migmatitic UGU nappe is cross cut by dextral-
699 reverse transcurrent shear zones and associated syntectonic peraluminous granodiorite and leucogranite plutons
700 (CPG and MPG) dated by TIMS U-Pb on zircon at 315 ± 4 and 311 ± 18 Ma, respectively (Gardien et al., 2011;
701 Solgadi et al., 2007; Vanderhaeghe et al., 2013), which provides a maximum age for the exhumation of these rocks.
702 The geochronological data obtained on the HP migmatites of the UGU in the Lyonnais and Livradois are
703 significantly younger than the ones obtained in the Sioule area and we propose to attribute these rocks to the central
704 nappe.

705

706 In the Haut-Allier area (Fig. 8 cross section CC'), the foliation of the UGU flattens to the south and delineates a
707 dome cored by migmatites attributed to the LGU (Burg and Matte, 1978; Gardien et al., 2011). In the Artense,
708 Truyere, and Marvejols regions, amphibolite facies paragneisses attributed to the LGU and greenschist facies
709 micaschists attributed to the PAU define an inverted metamorphic gradient with respect to the overlying UGU
710 (Ledru et al., 1989; Mercier et al., 1991a). Amphibolites of the UGU contain thin tonalitic to trondhjemitic layers
711 interpreted to reflect high-pressure partial melting (Nicollet and Leyreloup, 1978; Pin and Lancelot, 1982). This
712 high-pressure metamorphism has been dated by zircon TIMS U-Pb analyses at $432\pm 20/-10$ Ma in the Haut Allier
713 (Ducrot et al., 1983), 415 ± 6 Ma in Marvejols (Pin and Lancelot, 1982) and at 413 ± 23 and 408 ± 7 by Pb-Pb on
714 zircon and a Sm-Nd whole rock and garnet isochron respectively in the Rouergue (Paquette et al., 1995).
715 Retrograde amphibolite facies metamorphism is recorded by lower intercepts defined by discordant U-Pb zircon
716 data at 345-340 Ma obtained on paragneisses and amphibolites (Pin and Lancelot, 1982). The UGU-LGU contact
717 is intruded by the Margeride laccolithic composite pluton (Couturié et al., 1979; Couturié and Caen-Vachette,

718 1980; Talbot et al., 2005). The main porphyritic monzogranite yields U-Pb zircon dates of 334 ± 9 Ma (Respaut,
719 1984) and of 311 ± 9 Ma (Laurent et al., 2017) and a U-Pb on monazite of 314 ± 3 Ma (Pin, 1979). The leucogranitic
720 facies cross cutting the monzogranite is dated by various methods from 307 to 298 (Couturié and Caen-Vachette,
721 1980; Lafon and Respaut, 1988; Monié et al., 2000). In the Vivarais (Fig. 8 cross section DD'), several klippen of
722 UGU made of migmatites including amphibolite enclaves overly paragneisses and orthogneisses of the LGU,
723 outlining an inverted metamorphic gradient (Gardien, 1993). Rocks of the UGU have recorded HT eclogitic to HP
724 granulitic metamorphic conditions up to 15 Kbar at c. 800 °C, followed by retrogression at 5 Kbar at c. 550 °C
725 (Gardien, 1993). The HP migmatitic gneisses and amphibolites of the UGU contain zircon with metamorphic rims
726 dated by U-Pb at 351.5 ± 3.0 Ma and 343.5 ± 2.6 Ma, respectively and interpreted to represent retrogression of the
727 eclogite into amphibolite facies after tectonic accretion during continental collision (Chelle-Michou et al., 2017).
728 The underlying paragneisses display low-pressure granulite facies metamorphism associated with widespread
729 partial melting dated at c.a. 308 Ma (Chelle-Michou et al., 2017). These zones in the Vivarais, Marvejols and
730 Rouergue, with an inverted metamorphic gradient might correspond to the southern tip of the UGU central nappe.
731
732 To the south of the Rouergue, the Najac eclogites have recorded a pressure of 15–20 Kbar and a temperature of
733 560–630 °C (Lotout et al., 2018). Eclogite-facies metamorphism is dated by U-Pb on zircon at 385.5 ± 2.3 Ma, by
734 Lu-Hf on garnet cores at 382.8 ± 1.0 Ma, and by a Sm-Nd amphibole-garnet-whole rock isochron of 376.7 ± 3.3 Ma.
735 Subsequent exhumation and cooling below c. 500 °C are constrained by an apatite U-Pb age at 369 ± 13 Ma. The
736 maximum temperature reached by these eclogites is significantly lower than the ones recorded by eclogites
737 enclosed in the granulite facies migmatites of the UGU. Moreover, geochronological data available for the Najac
738 eclogites point to burial coeval with the UGU central nappe exposed in the Haut-Allier, Marvejols and Rouergue,
739 but also for a much older exhumation. These data suggest that the Najac eclogites are part of a nappe equivalent
740 to the MAU, which has a different P-T-t history than the UGU.
741
742 The Velay and Montagne Noire migmatite domes correspond to the lowermost exposed structural level of the E-
743 FMC (Fig. 4, Fig. 8 cross section CC', DD'). These migmatites originated by partial melting of paragneisses and
744 orthogneisses under MP to LP conditions at the bottom of the nappe pile from c. 320 to c. 300 Ma (Barbey et al.,
745 1999, 2015; Downes et al., 1997; Ledru et al., 2001; Montel et al., 1992b; Villaros et al., 2018; Williamson et al.,
746 1996) and contain dismembered enclaves of vaugnerites (Couzinié et al., 2013; Ledru et al., 2001; Michon, 1987;
747 Sabatier, 1991). The 100 km-wide, first-order Velay dome is delineated by the foliation of the surrounding
748 paragneisses and orthogneisses (Lagarde et al., 1994). The synmigmatitic foliation defines subdomes with an

749 average diameter of 10-20 km and characterized by a radial distribution of the HT mineral lineation (Ledru et al.,
750 2001). Accordingly, the Velay dome is a crustal-scale structure interpreted to represent the exhumed middle part
751 of the orogenic crust. The western boundary of the dome is subvertical and its southern part is overturned toward
752 the south (Burg and Vanderhaeghe, 1993; Ledru et al., 2001; Vanderhaeghe et al., 1999). Along the eastern side
753 of the dome, in the Vivarais region, the symigmatitic foliation is shallow-dipping and small klippen of the HP
754 migmatites belonging to the UGU central nappe, as described above, are exposed above LGU grading into MP to
755 LP migmatites (Chelle-Michou et al., 2017; Gardien, 1993; Gardien and Lardeaux, 1991; Gay et al., 1982). The
756 superposition of the HP migmatites attributed to the UGU on top of the LGU is inferred to represent an inverted
757 metamorphic gradient preserved from the time of the nappe emplacement. In turn, the downsection transition from
758 mid-amphibolite facies metamorphism documented in the LGU just beneath the UGU to MP and LP migmatites
759 of the Velay dome corresponds to a normal metamorphic gradient marked by an important increase in temperature
760 with depth.

761
762 The northern part of the Velay dome is delimited by the Pilat mylonitic low-angle detachment intersected by high
763 angle cataclastic normal faults (Gardien et al., 1997; Malavieille et al., 1990). Heterogeneous granite (i.e. diatexites)
764 in the core of the dome shows a relatively tight cluster of U-Pb ages on zircon and monazite, in the range of 307 ± 2
765 to 301 ± 5 Ma (Chelle-Michou et al., 2017; Couzinié et al., 2013; Laurent et al., 2017; Mougeot et al., 1997).
766 Magmatic cores with ages ranging from 390 to 340 Ma and surrounded by rims dated between 330 and 300 Ma
767 (Laurent et al., 2017) point to a protracted history of zircon growth and/or dissolution-reprecipitation in these
768 diatexites. To the north of the Velay the Gouffre d'Enfer syntectonic granite, emplaced within the Pilat detachment,
769 yielded an unprecise whole rock Rb-Sr age of 322 ± 26 Ma (Caen-Vachette et al., 1984; Vitel, 1988). To the south
770 of the Velay dome, a Rb-Sr isochron of 302 ± 4 Ma has been obtained for the Rocles syntectonic granite (Caen-
771 Vachette et al., 1981) emplaced in a detachment that has been overturned later on (Bouilhol et al., 2006; Burg and
772 Vanderhaeghe, 1993; Vanderhaeghe et al., 1999). U-Th-Pb ages by EMPA on monazite of 324 ± 4 Ma and 325 ± 5
773 Ma have also been obtained for the the Rocles granite (Bé Mézémé, 2005; Bé Mézémé et al., 2006), which overlap
774 with a more reliable U-Pb zircon LA-ICPMS data of 320.3 ± 3.8 Ma (Couzinié, 2017). This suggests that while the
775 Rocles granite was emplaced at c. 320 Ma, the Rb-Sr system was probably reset at 302 Ma. Migmatites and
776 heterogeneous granite of the core of the dome are intruded by small plutons and dykes of CPG/MPG with sharp
777 contacts designated as late-migmatitic (Montel and Abdelghaffar, 1993) dated by U-Th-Pb on monazite (LA-
778 ICPMS) from 307 ± 2 to 297 ± 4 Ma (Didier et al., 2013). They are characterized by an aluminous and potassic
779 signature and are rich in rounded enclaves of metapelites and of microdiorite suggesting a metapelitic source

780 together with a contribution from a magma generated by partial melting of an enriched mantle. Microgranites with
781 similar chemical signatures have yielded identical U-Th-Pb EMPA ages on monazite at about 300 Ma (306 ± 12 ,
782 291 ± 9 Ma) but also at about 255 Ma (257 ± 8 and 252 ± 11 Ma), which points to either a Permian crystallisation or
783 to hydrothermal perturbation at this time (Montel et al., 2002). High-angle normal faults rooting in the low-angle
784 detachments, delimit the late Carboniferous St. Etienne, Jaujac and Alès extensional basins filled by coarse detrital
785 sediments including clasts from the migmatites and granites interbedded with volcanic deposits (rhyolitic ash fall
786 tuffs and accretionary lapilli) and coal-bearing sediments (Becq-Giraudon et al., 1996).

787

788 The Montagne Noire is characterized by a dome structure with a core of migmatitic gneisses and a mantle of low-
789 grade metasedimentary rocks (Arthaud et al., 1966; Demange, 1980; Demange and Jamet, 1985; Ellenberger, 1967;
790 Engel et al., 1978, 1981; Gèze, 1949). Migmatites and orthogneisses in the core of the dome display a prolate finite
791 strain ellipsoid indicative of constriction with a subhorizontal long axis parallel to the axis of the elliptical shape
792 dome (Echtler and Malavieille, 1990; Matte et al., 1998; Rabin et al., 2015). Migmatites coring the Caroux dome
793 in the Montagne Noire have recorded P-T conditions of 6 Kbar and 720 °C (Rabin et al., 2015) and they are
794 juxtaposed to low-grade LP/HT micaschists (Demange and Jamet, 1985; Thompson and Bard, 1982). Magmatic
795 zircon from the migmatites yield U-Pb ages spreading from c. 330 to c. 300 Ma (Faure et al., 2014; Franke et al.,
796 2011; Roger et al., 2015). Migmatites contain mafic enclaves that have preserved relicts of eclogite facies
797 metamorphism (Demange, 1980; Faure et al., 2014). Zircon grains from the eclogite facies rocks yield two age
798 peaks, one at c. 360 Ma and the other at c. 315 Ma, with a few discordant ages pointing at an early Paleozoic
799 heritage (Faure et al., 2014; Whitney et al., 2015). Faure et al. (2014) attribute the 360 Ma age to eclogite facies
800 metamorphism whereas Whitney et al. (2015), based on REE signatures of the different zircon zones, argue that
801 eclogite facies is recorded by the 315 Ma age. The Montalet syntectonic granite emplaced along the northern side
802 of the Montagne Noire yield a U-Pb age on zircon of 294 Ma (Poilvet et al., 2011). This syntectonic granite is
803 juxtaposed to the late Carboniferous Graissessac basin along a mylonitic to cataclastic detachment (Van Den
804 Driessche and Brun, 1992). Many different models have been proposed for the Montagne Noire, the dome structure
805 having been interpreted as (i) an anticline developed by horizontal shortening (Matte et al., 1998)(Fig. 7), (ii) a
806 ductile layer exhumed in a pull-apart basin (Nicolas et al., 1977; Rey et al., 2011; Whitney et al., 2015), (iii) a
807 diapir (Charles et al., 2009), (iv) an eroded antiformal stack (Malavieille, 2010) or (v) a Metamorphic Core
808 Complex formed as a consequence of gravitational collapse of the Variscan belt during convergence (Aerden and
809 Malavieille, 1999; Aerden, 1998; Echtler, 1990; Echtler and Malavieille, 1990) or during regional extension (Van
810 Den Driessche and Brun, 1992).

811

812 **3. Previous tectonic-geodynamic reconstructions and debated issues**

813

814 In this section, we present the various tectonic-geodynamic reconstructions that were proposed at the scale of the
815 Variscan belt with a focus on the French Massif Central, with the idea of identifying robust features but also to
816 point at the discrepancies and shortcomings.

817

818 *Monocyclic doubly-vergent orogen model*

819

820 Early geodynamic reconstructions at the scale of Western Europe invoked a doubly-plunging subduction system
821 based on the presence of the two major suture zones described above, namely the Rhenic suture and the Medio-
822 European suture, and opposite vergence of structures on the northern and southern sides of the orogenic belt (Matte,
823 1986, 1991, 2001)(Fig. 2a). According to the latest version of this model, Silurian subduction of Ordovician
824 oceanic basins along the southern branch of the Variscan Belt was followed by Devonian continental subduction
825 and Carboniferous collision between Laurussia and Gondwana (Matte, 2001). This model, mostly relying on a
826 synthesis of structural, metamorphic and sedimentary data, provides a first order tectonic-geodynamic framework
827 for the Variscan belt. In contrast, other geodynamic models assuming that Armorica remained attached to the north
828 Gondwana margin do not include the closure of a Medio-European Ocean (e.g. Nance et al., 2010) and thus fail to
829 account for the presence of ophiolitic assemblages to the south of Armorica. Still, the reconstructions proposed by
830 Matte (1986; 1991; 2001) elude some key features including (i) the presence of a late Devonian arc and back-arc
831 association in the Vosges (Skrzypek et al., 2012) and the Eastern Massif Central (Somme and Brévenne Units, see
832 above); (ii) the mechanisms of exhumation of eclogites and migmatites, and, most of all, (iii) syn-orogenic partial
833 melting and magmatism that are notably absent from the cross sections despite the vast exposed surface represented
834 by migmatites and granites. Note also that in the scenario proposed by Matte (1986; 1991; 2001), the HP rocks of
835 the UGU are issued from the southern margin of Armorica, i.e. the upper plate relative to Silurian-Devonian
836 subduction. Accordingly, from their position, it is unclear how these rocks could have been buried to granulite
837 facies and then exhumed back to the surface.

838

839 *Polycyclic orogenic model*

840

841 Faure et al. (2008, 1997) refined the geodynamic model elaborated by Matte (1986, 1991, 2001) in order to account
842 for the late-Devonian magmatic arc and back-arc inferring a southward subduction of the Rhenic Ocean based on

843 the relative position of the Somme Unit to the north of the Brévenne Unit (Fig. 3). These authors propose a
844 polycyclic model for the tectonic evolution of the Variscan belt in Western Europe with two distinct orogenic phases
845 (Fig. 2b). The first orogenic phase is associated with northward oceanic subduction during the Silurian and
846 Devonian leading to the closure of the Medio-European Ocean followed by continental subduction during the early
847 Devonian and exhumation of the UGU before the late Devonian. This model provides an explanation for high-
848 pressure metamorphism, which is attributed to burial of rocks from the Gondwana margin that first have been
849 dragged with the downgoing plate and then decoupled from it allowing their exhumation. It should be noted that
850 mafic and ultramafic rocks of the LAC are described by Faure et al. (2008) as part of the UGU but are not
851 considered to represent an ophiolite, which is at odds with the interpretations of most authors. For example, to
852 explain the intimate association of mafic and felsic HP rocks, Lardeaux (2014) proposes that the UGU and the
853 LAC represent the formerly thinned continental margin of Gondwana (Fig. 2b). Irrespective of these differences,
854 all these authors invoke a second orogenic phase associated with southward subduction of the Rheic Ocean during
855 the late Devonian beneath an upper plate, made of the exhumed, HP UGU nappe. The latter undergoes extension
856 as attested by the late Devonian Brévenne back-arc rift basin (Fig. 2b). In this model, partial melting of the UGU
857 is attributed to retrogression owing to decompression during syn-orogenic exhumation whereas partial melting of
858 the underthrust LGU is interpreted to be caused by burial beneath the UGU (Fig. 2b). At the lithospheric scale,
859 a high-velocity anomaly beneath the Paris Basin detected in tomographic models is proposed to represent a
860 remnant of this southward subducting slab (Averbuch and Piromallo, 2012). As an alternative, Lardeaux et al.
861 (2001) advocated that the late Devonian Brévenne back-arc basin was opened above a northward subducting slab
862 (corresponding to the former Medio European Ocean) at the time of exhumation of the UGU and was closed as a
863 consequence of collision between Armorica and Gondwana. Despite differences in the polarity of subduction, all
864 these authors attribute Carboniferous deformation, metamorphism and magmatism in the French Massif Central
865 to crustal thickening owing to post Devonian continental collision followed by delamination of the lithospheric
866 root beneath the orogenic belt (Faure et al., 2002; Lardeaux et al., 2001; Lardeaux, 2014; Lardeaux et al., 2014).
867 This model considers implicitly that the UGU represents a single nappe exhumed and emplaced above the LGU
868 before the opening of the late Devonian Brévenne back-arc basin.

869

870 *Collision versus syn-orogenic extension during the Carboniferous*

871

872 The tectonic-geodynamic setting leading to the construction-evolution of the Variscan belt has also been actively
873 debated for the Carboniferous period. The mid- to late-Carboniferous is marked by (i) regional-scale strike-slip
874 shear zones and a NW-SE trending stretching lineation parallel to the belt throughout the French Massif Central

875 (Arthaud and Matte, 1975; G ebelin et al., 2007, 2009; Lardeaux and Dufour, 1987; Mollier and Bouchez, 1982);
876 (ii) the exhumation of metamorphic rocks and the emplacement of syntectonic plutons beneath low-angle
877 detachments (Faure and Pons, 1991; Roig and Faure, 2000); and (iii) fold and thrust belts in the foreland of the
878 Variscan belt as exemplified in the Ardennes (Sintubin et al., 2009) and in the Montagne Noire (Echtler, 1990).
879 These features have been interpreted as reflecting either lateral escape of crustal blocks during progressive
880 construction of the orogenic belt following continental collision (Arthaud and Matte, 1975; Burg et al., 1987;
881 G ebelin et al., 2007; Lardeaux and Dufour, 1987; Matte, 1986), syn-orogenic extension of the thickened orogenic
882 crust (Burg et al., 1993; Faure, 1995), or syn-convergent extension (G ebelin et al., 2009).
883
884 For the late Carboniferous-Permian period, gravitational collapse of the Variscan belt has been recognized through
885 the development of a rift system superimposed on the thickened crust (M enard and Molnar, 1988) and by the
886 identification of low-angle detachments in the French Massif Central (Bouilhol et al., 2006; Burg et al., 1993;
887 Faure, 1995; Gardien et al., 1997; Malavieille et al., 1990; Vanderhaeghe et al., 1999). For the same late
888 Carboniferous period, the prevailing tectonic-geodynamic model for the nearby Pyr en ees, south of the FMC,
889 favours a context of transpression (Cochelin et al., 2017; Den ele et al., 2014; Gleizes et al., 1997; Laumonier et
890 al., 2010) although models invoking regional extension have also been proposed (Gibson, 1991; Wickham et al.,
891 1987). On the other hand, a synthesis at the scale of western Europe reveals that the late Devonian to early-mid
892 Carboniferous (Visean) sedimentary record, preserved locally in the internal zone and in the foreland of the
893 Variscan belt, is dominated by platform carbonates and pelagic deposits, which is not in favour of the presence of
894 a Tibetan-type elevated orogenic plateau for this time period and questions the pertinence of the concept of
895 orogenic collapse applied to the Variscan belt (Franke, 2014). Nevertheless, these Visean carbonate deposits have
896 not been identified in the intermediate part of the French Massif Central, in between the Br evenne region and the
897 Montagne Noire. The near absence of late Devonian to middle Carboniferous deposits in the W-FMC, contrasts
898 with their abundance in the E-FMC and suggests either that it was at higher altitude at this time or that these
899 deposits have been eroded. At last, as pointed by Franke et al. (2011), it should be noted that foreland deposits are
900 underlain in the Montagne Noire and in the Pyr en ees by rocks affected by HT/LP metamorphism and deformation
901 during the Variscan orogeny, which are not typical characteristics of external zones of orogenic belts.

902

903 *Impact of partial melting and magmatism on Variscan tectonics?*

904

905 Despite the predominance of plutonic and migmatitic rocks in the French Massif Central, and more generally in
906 the Variscan belt (Zwart, 1967), early tectonic models partly eluded the relationships between HT metamorphism,

907 magmatism and orogenic evolution (Matte, 1986, 1991). During the 80's, progress on experimental petrology and
908 thermodynamic modelling (Gardien et al., 1995; Spear and Cheney, 1989; Vielzeuf and Holloway, 1988; Wyllie,
909 1977) has allowed to identify the P-T conditions of partial melting during orogenic evolution and discuss their
910 tectonic-geodynamic significance (England and Thompson, 1984; Thompson and Connolly, 1995). In the French
911 Massif Central, partial melting has been identified throughout the high-grade nappe pile and is associated with HP,
912 MP and LP metamorphism. High-pressure granulite to amphibolite facies migmatites dated in the early to middle
913 Devonian are interpreted to record either partial melting during exhumation of the UGU (Faure et al., 1997, 2008)
914 or to magmatic arc accretion (Lardeaux, 2014). Intermediate pressure migmatites typically associated with
915 Barrovian metamorphism with ages spreading from the middle Devonian to the middle Carboniferous (from c.
916 370 to c. 310 Ma) are interpreted as reflecting continental collision marked by nappe emplacement (Barbey et al.,
917 2015; Faure et al., 2008; Ledru et al., 1994; Montel et al., 1992b) and/or a mantle heat supply owing to
918 asthenospheric upwelling as a consequence of lithospheric delamination (Faure et al., 2002, 2009a). The last partial
919 melting event is characterized by low-pressure migmatites and granites exposed in large domes is attributed to a
920 temperature increase caused by the emplacement of mantle-derived magmas (vaugnerites) during late-orogenic
921 collapse (Barbey et al., 2015; Ledru et al., 1994; Montel et al., 1992). Each of these migmatite types are therefore
922 dominantly regarded as recording discrete, short-lived events of partial melting associated with prograde
923 metamorphism. This is in conflict with the fact that the solubility of accessory minerals in silicate liquids during
924 melting and crystallization is positively correlated with temperature (Boehnke et al., 2013; Harrison and Watson,
925 1983; Watson and Harrison, 1983). Consistently, thermodynamic modelling shows that zircon and monazite, the
926 most common geochronometers in migmatites, preferentially crystallize during the retrograde (cooling) path and
927 only seldom preserve a record of the prograde path (Kelsey et al., 2008; Yakymchuk and Brown, 2014).

928
929 The discrepancies between tectonic and geodynamic models proposed for different parts of the Variscan belt of
930 Western Europe illustrate the difficulty in tracking the continuity of terranes and sutures. They potentially point to
931 a non-cylindrical structure marked by discontinuous ribbon-shaped continental terranes separated by immature
932 oceanic basins. Furthermore, these discrepancies reflect differences in the interpretation of the geological record
933 in terms of metamorphism, magmatism and deformation. Until now, the existing models have failed to integrate
934 the impact of partial melting and of the generation of magmatic rocks on orogenic evolution. We hereby provide
935 a novel synthetic model for the geodynamic-tectonic evolution of the Variscan belt integrating most of the existing
936 data summarized in the previous paragraphs. In contrast with previous models, we emphasize the pivotal role of

937 protracted partial melting and magmatism on the rheology of the orogenic crust and thus on the tectonic-
938 geodynamic evolution of the Variscan belt.

939

940 **4. A new model for the geodynamic-tectonic evolution of the Variscan belt of Western** 941 **Europe**

942 **4.1. Pre-Variscan configuration: the North Gondwana hyper-extended margin**

943

944 As presented in section 2.1, the relative position of the cratons, the numbers and sizes of continental terranes and
945 oceanic basins, and the polarity of subductions are all actively debated owing to discrepancies between
946 paleomagnetic and paleobiostratigraphic data, and to uncertainties in tectonic reconstructions. The ophiolitic
947 assemblages with different protolith and peak ages as well as contrasting peak temperatures identified in the
948 French Massif Central, in the Armorican Massif, and in the Vosges (Ballèvre et al., 2009; Berger et al., 2010a;
949 Bernard-Griffiths and Cornichet, 1985; Bosse et al., 2000; J. P. Burg et al., 1989; Dubuisson et al., 1989; Girardeau
950 et al., 1986; Hanmer, 1977; Lardeaux et al., 2001; Lotout et al., 2018; Mercier et al., 1991a; Santallier et al., 1988;
951 Skrzypek et al., 2012), might represent different sutures that might have corresponded to former rift and/or oceanic
952 basins separating former crustal blocks. This scheme is consistent with the pre-Variscan record of the micaschists,
953 paragneisses and orthogneisses forming the UGU, MAU, LGU and their relative para-autochthon exposed in the
954 French Massif Central and the Pyrénées (Fig. 5, Table 1). Namely, Ediacarian sediments intruded by Cambrian
955 granitic plutons, represent a Cadomian basement for the thick detrital sedimentary sequences of lower Paleozoic
956 age deposited during the post-Pan-African dislocation of the Gondwana continent (Alexandrov et al., 2001; Chelle-
957 Michou et al., 2017; Couzinié et al., 2017, 2019, Duthou et al., 1981, 1984; R’Kha Chaham et al., 1990). Other
958 orthogneisses with intrusive contacts (dike networks, contact metamorphism) of Ordovician age, represent former
959 laccoliths emplaced during extension along the northern margin of the Gondwana continent (Barbey et al., 2001;
960 Bernard-Griffiths, 1975; Bernard-Griffiths et al., 1977; Castiñeiras et al., 2008; Cocherie et al., 2005; Deloule et
961 al., 2002; Duthou et al., 1981, 1984; Lasnier, 1968; Lotout et al., 2017; Melleton et al., 2010; Pin and Marini, 1993;
962 R’Kha Chaham et al., 1990; Roger et al., 2004). The calc-alkaline to tholeiitic chemical signature of the LAC also
963 suggests an emplacement of this bimodal magmatic suite in a continental to oceanic rift environment during the
964 Cambrian-Ordovician (Bodinier et al., 1986; Briand et al., 1995; Chelle-Michou et al., 2017; Pin and Lancelot,
965 1982). Pre-Neoproterozoic rocks, such as the Archean to Paleoproterozoic Icartian gneisses exposed in the
966 northern Armorican Massif (D’Lemos et al., 1990; Le Corre et al., 1991), have not been identified in the French

967 Massif Central. As already mentioned by other authors (Bouchardon et al., 1989; Faure et al., 1997; Franke et al.,
968 2017; Lardeaux, 2014; Pin, 1990), these data are consistent with the development of a thinned continental margin
969 with one or several immature rifts and/or oceanic basins along the hyperextended northern continental margin of
970 the Gondwana craton.

971
972 Accordingly, a two-stage geodynamic model is proposed for the pre-Variscan configuration of the French Massif
973 Central. During the Cambrian (Fig. 16a, 17a), subduction of the Iapetus Ocean along the Gondwana margin was
974 marked by the emplacement of calc-alkaline plutonic and volcanosedimentary rocks (D'Lemos et al., 1990; Le
975 Corre et al., 1991). Crustal extension and opening of rifts at the rear of this active margin during the Ordovician
976 might have been favoured by retreat of the Iapetus slab leading to the opening of the Medio-European Ocean (Fig.
977 16b, 17b). Such a hyper-extended margin might have spread over several hundred kilometres from the Ordovician
978 to early Silurian and might conciliate the apparent contradiction between paleomagnetic reconstructions implying
979 a distance of more than 2000 km between Gondwana and Laurussia during the Ordovician and paleontologic data
980 pointing to small communicating basins. Accordingly, the Variscan orogenic belt is essentially made of a reworked
981 continental crust made of a Cadomian basement affected by post Pan-African Ordovician hyper-extension,
982 intruded by granitoids and covered by thick volcanic-sedimentary series. Reworking of this hyper-extended margin
983 occurred as a consequence of convergence between Laurussia and Gondwana from the Silurian to the
984 Carboniferous (Fig. 17c-e).

985 **4.2. Late Silurian to Devonian subduction and HP partial melting of terranes issued** 986 **from the North Gondwana margin**

987
988 As described in the previous sections, the oldest evidence for the onset of the Variscan orogenic cycle corresponds
989 to the HP metamorphism identified in mafic and ultramafic rocks of the LAC (Fig. 4) pointing to subduction of
990 these units (Bouchardon et al., 1989; Gardien et al., 1990; Lasnier, 1968, 1971; Pin and Vielzeuf, 1983). The
991 presence of UHP mineral assemblages in the LAC of the Lyonnais (Lardeaux et al., 2001) and Limousin (Berger
992 et al., 2010a, 2010b), argues for burial of these units to a depth of more than 100 km. Nevertheless, two types of
993 eclogites are distinguished, namely (i) HT eclogites that are forming enclaves-boudins into migmatites of the UGU
994 as exemplified in the Aigurande, north Limousin, Sioule, Livradois, Lyonnais, Rouergue regions (Burg et al., 1989;
995 Dufour, 1985; Faure et al., 2008; Gardien, 1990; Gardien et al., 1990; Lardeaux et al., 2001; Pin and Vielzeuf,
996 1983); and (ii) LT eclogites that are hosted by micaschists not affected by partial melting as illustrated by the MAU

997 exposed in south Limousin or in Najac (Berger et al., 2010a; Lotout et al., 2018). According to the few available
998 geochronological data, subduction of these units is diachronous and occurred from the late Silurian to the Devonian
999 (Fig. 18a-c)(Berger et al., 2010a; Do Couto et al., 2016; Ducrot et al., 1983; Lotout et al., 2018; Paquette et al.,
1000 1995; Pin and Lancelot, 1982).

1001
1002 A similar nappe pile has been described in the South Armorican Massif, with the distinction of HT and LT eclogites
1003 (Ballèvre et al., 2009). The core of the Champtoceaux nappe is made of granulite facies migmatitic gneisses, with
1004 enclaves of ultramafic rocks with HT eclogite facies relics (Ballèvre et al., 1987, 2002; Godard, 2001; Marchand,
1005 1981). These rocks overlay lower grade orthogneisses and micaschists that contain mafic boudins with LT eclogite
1006 facies relics. LT eclogites and blueschist facies rocks of the Ile de Groix are in a similar structural position as the
1007 MAU in the FMC and have been interpreted to represent the suture of the Galicia-South Brittany Lower Paleozoic
1008 Ocean. $^{40}\text{Ar}/^{39}\text{Ar}$ and Rb-Sr dating of blueschist facies rocks, yield c. 360 Ma for the metamorphic peak attributed
1009 to subduction of this ocean at the Devonian-Carboniferous transition. Greenschist facies retrogression of these
1010 rocks reflects cooling and exhumation dated in the early Carboniferous as constrained by ages ranging from 355
1011 to 340 Ma (Bosse et al., 2000, 2005; Paquette et al., 2017).

1012
1013 Mafic-ultramafic enclaves with relictual HT eclogitic facies metamorphism enclosed in granulite facies migmatites
1014 was also identified in other Variscan massifs. In the Vosges, garnet-lherzolite belonging to a subcontinental
1015 lithospheric mantle exhumed from more than 150 km are present in the varied gneiss unit dominated by granulite
1016 facies migmatitic gneiss (Altherr and Kalt, 1996; Brueckner and Medaris, 2000; O'Brien and Rötzler, 2003). The
1017 Bohemian massif also comprises large mafic and ultramafic bodies enclosed in high-grade gneisses (Kusbach et
1018 al., 2012). In the French Massif Central, ages interpreted to record eclogite facies peak metamorphism are typically
1019 20 to 30 Ma older to the ones attributed to granulite facies metamorphism and partial melting of their host
1020 migmatitic paragneisses and orthogneisses (Chelle-Michou et al., 2017; Duthou et al., 1981, 1994; Pin and
1021 Lancelot, 1982).

1022
1023 The significance of this association and of this age gap is debated. The question is whether it represents (i) a pre-
1024 metamorphic association reflecting intrusion of mafic magmas into the crust or tectonic accretion of oceanic and
1025 continental terranes, (ii) a syn-metamorphic extrusion of mantle into the lower crust, (iii) or a subduction of the
1026 continental crust and mixing of mantle and crustal units. Tectonic-geodynamic models attributing the succession
1027 of eclogite and granulite facies metamorphism to oceanic subduction followed by continental collision (Dubuisson

1028 et al., 1989; Girardeau et al., 1986; Lardeaux et al., 2001; Ledru et al., 1989; Matte, 1986) provide an explanation
1029 for the HP metamorphic condition but do not account for the systematic incorporation of the LAC into the
1030 migmatitic UGU. Models invoking a vertical extrusion of the mantle into the partially molten granulitic lower
1031 crust account for the presence of mafic and ultramafic rocks into the migmatitic continental rocks but do not
1032 propose a driving force for such a process (Kusbach et al., 2012). A more appealing proposition is that pieces of
1033 suprasubduction mantle might be incorporated into the orogenic belt during relamination of orogenic crust by flow
1034 of partially molten crustal units decoupled from the downgoing slab (Kusbach et al., 2015; Lexa et al., 2011).
1035 Another option is that the association of remnants of an oceanic suture together with lithospheric mantle into
1036 granulite facies migmatitic gneisses, was achieved by mixing of subducted units into the mantle (Faure et al., 2008;
1037 O'Brien and Rötzler, 2003). In this latter scenario, granulite-facies partial melting of the UGU would be driven
1038 either by decompression of the UGU during syn-orogenic exhumation (Faure et al., 2008) or owing to thermal
1039 relaxation about 30 Ma after subduction (O'Brien and Rötzler, 2003). We concur to the latter proposition as it will
1040 be developed in the next section.

1041

1042 **4.3. Middle Devonian to early Carboniferous syn-orogenic exhumation of the** 1043 **partially molten subducted crustal units with mantle enclaves**

1044

1045 The geological record of the middle Devonian to early Carboniferous period is marked by the association of HT
1046 eclogites and HP granulite-facies migmatites of the UGU. These are only present south of the Nort sur Erdre Fault
1047 in the Armorican Massif and of the Lalaye-Lubine Fault in the Vosges Massif (Fig. 1), which delineate the main
1048 suture south of the Armorica-Barrandia continental block (Faure et al., 1997). North of this suture, the inprint of
1049 Variscan metamorphism is absent or limited. The typical retrogression and transposition of the granulite facies
1050 mineral assemblage and foliation of the UGU into an amphibolite facies foliation records isothermal
1051 decompression caused by rapid exhumation (Burg et al., 1989; Dufour, 1985; Faure et al., 2008; Gardien et al.,
1052 1990; Lardeaux et al., 2001; Mercier et al., 1991; Pin and Vielzeuf, 1983)(Fig. 4). The position of the exhumed
1053 high-grade nappes relative to the Nort sur Erde Fault and Lalaye-Lubine Fault implies that this suture was reworked
1054 as a steep syn-orogenic detachment allowing the exhumation of the continental units previously entrained in
1055 subduction and then decoupled from the slab (Fig. 18b,c). The inverted metamorphic gradient at the contact
1056 between the UGU and the LGU (Burg et al., 1984; Burg et al., 1989; Nicollet, 1978; Schulz et al., 2001) suggests
1057 that the exhumation of the UGU is associated with burial of the LGU. This is consistent with transposition of the

1058 granulite facies foliation of the UGU into an amphibolite facies synmigmatitic foliation (Burg and Matte, 1978;
1059 Forestier, 1961) and with the absence of HP/HT eclogitic relicts in the LGU. Thrusting of the UGU over the LGU
1060 is locally corroborated by kinematic data indicating a top-to-the SE sense of shear (Burg et al., 1984; Faure et al.,
1061 1979, 2009a). However, this contact is in many places reworked and retrogressed into a greenschist facies fabric
1062 associated with a top-to-the NW sense of shear attributed to regional extension leading to exhumation of the LGU
1063 and of the PAU (Faure et al., 1979, 2008, 2009a).

1064
1065 Available geochronological and stratigraphic data indicate that exhumation of the UGU started before the late
1066 Devonian with the emplacement of the northern nappe exposed in the Aigurande plateau, the Morvan area, and
1067 sampled in the Couy borehole (Boutin and Montigny, 1993; Costa and Maluski, 1988; Godard, 1990). The
1068 exhumation of the UGU forming the central and southern nappe (Limousin, Sioule-Combrailles, Livradois – Haut-
1069 Allier, Lyonnais) is bracketed between the late Devonian and the Visean and thus postdates the exhumation of the
1070 northern nappe (Chelle-Michou et al., 2017; Do Couto et al., 2016; Gardien et al., 2011; Melleton et al., 2009; Pin
1071 and Lancelot, 1982). Migmatitic paragneisses from the Limousin and the Sioule display a subhorizontal foliation
1072 bearing a NW-SE trending lineation mostly associated with top-to-the-NW kinematic criteria interpreted to
1073 accommodate syn-orogenic exhumation of the UGU (Bellot and Roig, 2007; Do Couto et al., 2016). In the
1074 Livradois, the foliation of the migmatites attributed to the UGU is steeply-dipping and is associated with dextral
1075 top-to-the SE kinematic criteria interpreted to record extrusion of the UGU (Gardien et al., 2011; Vanderhaeghe
1076 et al., 2013). Such a mechanism of vertical extrusion for the formation of high-grade nappes is consistent with the
1077 interpretation of the Champtoceaux nappe, in the Armorican Massif, as a fold nappe (Ballèvre et al., 2009) and
1078 has also been proposed to account for the structure of the varied gneiss unit in the Vosges (Skrzypek et al., 2014)
1079 and the Bohemian Massif (Schulmann et al., 2014).

1080
1081 Several lines of reasoning suggest that the multiple nappes model is more coherent with the hyperextended margin
1082 model made of thinned continental blocks separated by small immature oceanic basins than with a pre-Variscan
1083 configuration characterized by a single, large oceanic domain between Gondwana and Armorica. First, the inverted
1084 metamorphic isograds, requiring limited thermal relaxation after underthrusting, fits better with a model
1085 considering a system of several small nappes with at most a few tens of kilometres of lateral expansion, rather than
1086 the case of a single, several hundred kilometres long nappe. Indeed, thermal-mechanical modelling of orogenic
1087 evolution indicates that inverted metamorphic/thermal gradients are not sustainable for more than about 100 km
1088 equivalent to about 10 Ma with a convergence rate of 1cm/yr (Henry et al., 1997; Huerta et al., 1996; Vanderhaeghe

1089 et al., 2003). Moreover, the multiple nappes model predicts diachronous HP metamorphism, which seems to be
1090 confirmed by the currently available geochronological data. Finally, the absence of large volumes of calc-alkaline
1091 magmatism associated with subduction initiation and steady-state subduction further suggests that forced
1092 subduction of several hyper-extended basins is a more likely scenario than the spontaneous subduction initiation
1093 of a mature oceanic crust (see McCarthy et al. 2018).

1094
1095 Following this rationale, following other authors, we propose that the construction of the Variscan orogenic belt
1096 was achieved by tectonic accretion of continental units that were previously subducted and then decoupled from
1097 the downgoing slab (Faure et al., 1997, 2008; Lardeaux et al., 2001) rather than by continental collision and
1098 indentation and thickening of the overriding plate as proposed in early tectonic reconstructions (Franke, 1989;
1099 Ledru et al., 1989; Matte, 1986). Again, available geochronological data for the UGU and LAC are consistent with
1100 partial melting at high-pressure (10-20 Kbars) of paragneisses, orthogneisses and amphibolites c. 20 to 30 Ma after
1101 subduction (Chelle-Michou et al., 2017; Duthou et al., 1981, 1994; Nicollet and Leyreloup, 1978; Pin and Lancelot,
1102 1982). Although such data are scarce and of unequal robustness from a nappe to another, this time span is broadly
1103 consistent with that required for thermal relaxation after burial (England and Thompson, 1984; Vanderhaeghe et
1104 al., 2003). Following models advocated for the tectonic accretion of HP mafic-ultramafic rocks enclosed in
1105 migmatitic units (Gordon et al., 2016; Labrousse et al., 2011; O'Brien and Rötzler, 2003; Závada et al., 2018), we
1106 propose that partial melting of subducted units forming the protolith of the UGU triggered their mechanical
1107 decoupling from the slab. In this scenario, mafic and ultramafic enclaves would represent fragments of previously
1108 subducted oceanic crust and lithospheric mantle entrained by the buoyant and low-viscosity, partially molten rocks,
1109 on their way back towards the surface. This process corresponds to syn-orogenic exhumation by vertical extrusion
1110 of the partially molten nappes. According to this proposition, the UGU represents the part of the thinned continental
1111 margin that has been subducted and then decoupled from the downgoing slab, while the LGU represents the part
1112 of the former continental margin that was underthrust beneath the UGU during its syn-orogenic exhumation.
1113 The age gradient for retrogression and cooling of the UGU, ranging from c. 385 Ma in the north to c. 340 Ma in
1114 the south, is consistent with progressive exhumation of nappes successively decoupled from a north-vergent and
1115 southward-retreating subduction slab (Fig. 18). We defined here a northern, central and southern nappe but this
1116 proposition and the number of nappes and of repeated UGU/LGU alternations remains to be clarified. Another
1117 consequence of partial melting of subducted fertile continental units might be the percolation of felsic melts into
1118 the suprasubduction mantle wedge, contributing to its enrichment in incompatible elements. Such a process might
1119 explain the signature of mafic magmas emplaced during the Carboniferous, as described in the next section.

1120

1121 **4.4. Late Devonian exhumation of nappes in between retreating slabs**

1122

1123 The geological record of the late Devonian period (Figs. 11; 18b,c) is marked by a great diversity of information
1124 that is difficult to reconcile in a single geodynamic context. In the northern part of the French Massif Central,
1125 plutonic and volcanic rocks (ACG) exposed respectively in the Somme and Limousin regions have been
1126 interpreted as a continental magmatic arc (Faure et al., 2008; Pin and Paquette, 1997). The tholeiitic to calc-alkaline
1127 volcanic rocks of the Brévenne Unit have been attributed to a back-arc rift basin (Bébién, 1971; Pin and Lancelot,
1128 1982; Sider and Ohnenstetter, 1986). Rocks of the same age and geochemical signatures exposed in the Central
1129 Bohemian Plutonic Complex have been interpreted as arc magmas originated in an Andean-type continental
1130 margin (Janoušek et al., 2004; Janousek and Holub, 1997; Schulmann et al., 2009). The positive ϵ_{Nd} of these
1131 magmatic rocks points to a dominant juvenile contribution (Fig. 14a). However, structural, metamorphic and
1132 geochronologic record demonstrate that the late Devonian is also marked by (1) the exhumation of the central
1133 nappe in the Limousin and Livradois (Bellot and Roig, 2007; Do Couto et al., 2016; Gardien et al., 2011; Melleton
1134 et al., 2009); and (2) the emplacement of cordierite-bearing peraluminous granite laccoliths (CPG) (Berthier et al.,
1135 1979; Bertrand et al., 2001; Cartannaz, 2006; Gébelin et al., 2009; Pin and Paquette, 1997). The crust-derived
1136 Guéret-type plutons formed through melting of dominantly metasedimentary sources, possibly with the
1137 contribution of a mafic igneous lower crust (Downes et al., 1997; Downes and Duthou, 1988). These data imply
1138 that the end of opening of the Brévenne rift and the construction of the Morvan continental arc, are coeval with
1139 partial melting of subducted continental units. Furthermore, this activity is contemporaneous to deposition of
1140 detrital sediments and carbonates in the underfilled southern foreland basin at the front of a propagating thrust
1141 system, currently exposed in the Pyrénées (Franke and Engel, 1986; Souquet et al., 2003).

1142

1143 To the south of Armorica, geochronological data obtained on blueschists exposed in the Ile de Groix and on low-
1144 temperature eclogites at the base of the Champtoceaux nappe indicate that high-pressure metamorphism attributed
1145 to subduction occurred at about 370-360 Ma (Bosse et al., 2000, 2005; Paquette et al., 2017). North of the Nort
1146 sur Erdre fault, the Saint Georges sur Loire unit, a late Silurian to early Devonian back-arc basin, affected by
1147 blueschist facies metamorphism, has also potentially been subducted at this time (Cartier et al., 2001; Ledru et al.,
1148 1986). Mid to late Devonian subduction, but with a southward dip, is likewise recorded north of the Medio-
1149 European suture, in the Saxo-Thuringian terrane to the north of the Vosges and of the Bohemian Massifs
1150 (Schulmann et al., 2014; Skrzypek et al., 2014). In the Vosges Massif the ligne des Klippes represents an immature

1151 oceanic basin opened during the late Devonian and inverted in the Lower Carboniferous (Skrzypek et al., 2012).
1152 North of Armorica, in South West England, the Lizard suture represents an early Devonian immature oceanic
1153 domain obducted during the early Carboniferous (Clark et al., 1998; Floyd and Leveridge, 1987; Shail and
1154 Leveridge, 2009).

1155
1156 Accordingly, late Devonian extension in the internal zone of the Variscan belt occurred in an overall context of
1157 plate convergence as implied by subduction/exhumation of nappes, foreland propagation of deformation and
1158 deposition of clastic sediments. Therefore, two geodynamic scenari are evoked to account for this extension,
1159 namely (i) opening of a back-arc associated with northward subduction of the Medio European Ocean being
1160 contemporary of the southward subduction of the Rheic Ocean followed by continental collision (monocyclic
1161 model, Lardeaux et al., 2001; Ledru et al., 1989; Matte, 1986), or (ii) renewed extension of the Eo-Variscan
1162 orogenic belt associated with southward subduction of the Rheic Ocean after closure of the Medio European Ocean
1163 by northward subduction (polycyclic model, (Faure et al., 1997, 2009a; Lardeaux, 2014; Lardeaux et al., 2014;
1164 Leloix et al., 1999; Pin, 1990). The cooling ages obtained on the UGU of the Aigurande plateau indicates that at
1165 least some of the high-grade nappes were exhumed to the surface before late Devonian rifting and emplacement
1166 of the Brévenne volcanics, which is more consistent with the polycyclic model.

1167
1168 Alternatively, to resolve the apparent discrepancy between an overall context of plate convergence and local
1169 extension, we propose that late Devonian geodynamics was characterized by convergence accommodated by
1170 subduction but also by retreat of the northern (Rheic) and southern (Medio-European) slabs. This explains
1171 simultaneous closure of immature oceanic basins entrained in subduction, tectonic accretion of ribbon-shaped
1172 terranes and extension of the upper plate. Hence, the exhumation of previously subducted continental units might
1173 have occurred without substantial erosion owing to the opening of space toward the surface in between the
1174 retreating slabs as envisioned in the conceptual models of Vanderhaeghe and Duchêne (2010). In this scenario, the
1175 top to the NW kinematic criteria marking the contact between the Brévenne Unit and the UGU of the Monts du
1176 Lyonnais, might have accommodated the last stage of syn-orogenic exhumation of the high-grade nappe as
1177 proposed for the exhumation of the UGU in the Limousin at the same period (Bellot and Roig, 2007).

1178
1179 However, this model does not fully account for lateral variations of the tectonic context, evidenced by exhumation
1180 of nappes and emplacement of peraluminous granites in the western French Massif Central coeval with opening
1181 of a continental to oceanic rift, in its eastern part. Two directions are proposed for future reflexion. The first one

1182 would be to consider a context of oblique plate convergence, which might allow for opening of pull-apart basins
1183 along releasing bends and concomitant burial and exhumation of tectonic units along restraining bends. The second
1184 one would be to infer differential retreat between the western and eastern side of the French Massif Central that
1185 might have been accommodated by a precursor of the Sillon Houiller strike-slip fault (Fig. 3). Slab retreat
1186 potentially controls the tectonic-magmatic geological history of the French Massif Central throughout the
1187 Carboniferous as described in the following sections.

1188

1189 **4.5. Carboniferous (c. 345-310 Ma) building of an orogenic plateau by lateral flow** 1190 **of the partially molten orogenic root**

1191

1192 The Carboniferous (345-310 Ma) geological record of the FMC is marked in the northern part by E-W to NW-SE
1193 trending regional-scale dextral strike-slip shear zones and orogen-parallel stretching localizing the emplacement
1194 of mantle and crust-derived magmas and in the southern part by thrusts and folds in the Cévennes, Albigeois and
1195 Montagne Noire, coeval with deposition of clastic sediments in the foreland (Figs. 1, 3, 12, 18d) (Arnaud and Burg,
1196 1993; Arthaud and Matte, 1975; Engel, 1984; Faure et al., 1999; Feist and Galtier, 1985). The strike-slip shear
1197 zones, exemplified in the Limousin, (Faure and Pons, 1991; Gèbelin et al., 2007, 2009; Mollier and Bouchez, 1982;
1198 Roig and Faure, 2000), in the Hermitage area (Barbarin and Belin, 1982), in the Livradois (Gardien et al., 2011;
1199 Vanderhaeghe et al., 2013), and in the Lyonnais (Lardeaux and Dufour, 1987), merge to the northwest with the
1200 South Armorican shear zone (Carlier De Veslud et al., 2004; Gèbelin et al., 2007; Lerouge and Quenardel, 1988;
1201 Rolin et al., 2009, 2014). As presented above, these strike-slip shear zones have been interpreted either to record
1202 a period of transpression (Gèbelin et al., 2007; Lardeaux and Dufour, 1987) or to reflect the transition from
1203 collision to orogen-parallel extension (Faure et al., 1993, 2009b; Ledru and Autran, 1987; Roig and Faure, 2000).

1204

1205 After a 10 Ma gap from c. 355 to c. 345 Ma, magmatism proceeded with the emplacement of plutonic and volcanic
1206 rocks throughout the middle Carboniferous (Fig. 12). In section 3.4, following previous authors (Barbey et al.,
1207 2015; Laurent et al., 2017; Moyen et al., 2017; Williamson et al., 1996, 1997), MPG and CPG (and their volcanic
1208 counterparts) are proposed to derive from a mixed crustal source comprising ortho- and paragneisses from the
1209 LGU. Partial melting of the orogenic root at this time is documented by MP migmatites dated at c. 315 Ma
1210 underlying the Millevaches granitic laccolith (Gèbelin et al., 2009) and by MP migmatites mantling the Velay
1211 dome with ages ranging from c. 330 Ma to c. 315 Ma (Be Mezeme et al. 2006; Cocherie et al. 2005; Mougeot et

1212 al. 1997). Although volumetrically less abundant, mantle-derived magmatism is expressed almost exclusively in
1213 the East Massif Central (only a few occurrences are described in Limousin) by the presence of widespread
1214 vaugnerites, forming decimeter- to kilometer-sized bodies intimately associated with the granites and migmatites.
1215 The dual geochemical character of vaugnerites (low SiO₂, high Mg# together with elevated K, LILE and LREE
1216 contents), as well as their Sr-Nd-Pb-Hf isotope signatures (Couzinié et al., 2016; Turpin et al., 1988), is consistent
1217 with partial melting of a lithospheric mantle that was previously enriched in incompatible elements (Couzinié et
1218 al., 2016; Sabatier, 1991; Solgadi et al., 2007; von Raumer et al., 2014). The variety of the geochemical signatures
1219 of some granitoids and the fact that they contain micromafic enclaves indicate a mixture of crustal-derived and
1220 mantle-derived magmas, as illustrated in the Livradois (Solgadi et al., 2007). This model would be particularly
1221 relevant to explain the origin of the compositionally intermediate KCG and, to a lesser extent CPG. The Margeride
1222 granite, for example, shows an intermediate signature, interpreted as reflecting interaction with mafic melts
1223 (Laurent et al., 2017; Williamson et al., 1992). Collectively, granites exposed in the eastern French Massif Central
1224 show the implication of different sources that are progressively affected by partial melting as the temperature of
1225 the orogenic root increases (Fig. 15). Geochronological data indicate that (i) granites and vaugnerites emplaced
1226 together from c. 340 to c. 300 Ma and (ii) there is a progressive younging of U-Pb emplacement ages of both
1227 granites and vaugnerites from the North (Forez, Lyonnais) to the South (Cévennes) in the considered time period,
1228 pointing to the southward migration of a lithospheric-scale thermal anomaly resulting in both crust- and mantle
1229 melting (Laurent et al., 2017).

1230
1231 In the North-Eastern Massif Central, the extrusive equivalents of the granitoids record a drastic shift in composition
1232 during the middle Carboniferous. They change from mafic, low to medium-K calc-alkaline to felsic and high K
1233 (potassic rhyolites, and associated microgranites), broadly similar to MPG in composition. These rhyolites are
1234 middle to upper Visean in age as constrained by a U-Pb zircon age of 336.9 ± 3.2 Ma (Cartannaz et al., 2007a),
1235 identical within uncertainty to the age of the underlying granitoids (Laurent et al., 2017). Moreover, both the early,
1236 and the middle Carboniferous magmatic rocks do include some mantle-related components, with nevertheless clear
1237 differences in the nature of the mantle component between these two periods (Fig. 14a). Up to the early
1238 Carboniferous (before c. 345—340 Ma), the isotopic composition of the mantle-derived magmatic rocks (late
1239 Devonian Brévenne and lower Carboniferous series) are on the mantle array, consistent with an asthenospheric
1240 mantle source. On the other hand, the middle (and late) Carboniferous mantle-derived magmatic rocks (vaugnerites
1241 and lamprophyres) are shifted towards “crustal” compositions, reflecting the growing influence of a recycled
1242 crustal component in the mantle below the French Massif Central. A similar and coeval evolution is described in

1243 the Bohemian Massif (Janoušek et al., 2004; Janousek and Holub, 1997). In the French Massif Central, there is
1244 not only a temporal evolution, but also a spatial distribution of mantle sources. While the enriched mantle is
1245 centered on the Velay complex, the non-enriched mantle domain is located in the Northern part of the region
1246 (Beaujolais and Morvan). Similarly, different mantle compositions are still featured today in mantle xenolith from
1247 Cenozoic volcanoes (Lenoir et al., 2000), displaying a comparable spatial distribution. Furthermore, the
1248 volumetrically more abundant Cenozoic magmatism occurs in the domain where the mantle is more enriched (and
1249 probably more fertile).

1250
1251 The preservation of platform carbonates of Visean age in the northern part of the French Massif Central and around
1252 the Montagne Noire, indicates that these regions were below sea level at this time. Other sedimentary sequences
1253 of this period corresponds to the erosion products of subcontemporaneous volcanics and plutonics trapping organic
1254 matter in continental basins delimited by strike-slip shear zones or normal faults (Bertaux et al., 1993; Bruguier et
1255 al., 1998; Thiéry et al., 2009).

1256
1257 In order to reconcile all observations, we propose that exhumation of migmatites along strike-slip shear zones
1258 coeval with foreland propagation of the deformation front correspond to growth of an orogenic plateau by lateral
1259 flow of the partially molten orogenic root in a context of plate convergence associated with southward slab retreat
1260 (Figs. 17; 18d). This plateau spreads from south of the Brévenne region to north of the Montagne Noire as
1261 constrained by the deposition of platform carbonates. In this model, the partially molten orogenic root also flows
1262 toward the north beneath the former late Devonian Brévenne rift basin. Such horizontal flow, already proposed for
1263 the Vosges (Skrzypek et al., 2014) and the Bohemian Massifs (Kusbach et al., 2015; Lexa et al., 2011; Schulmann
1264 et al., 2014), explains the voluminous granitic magmatism observed at that time. The systematic occurrence of
1265 vaugnerites along with granitic magmas point to mantle melting that might be caused by decompression as a
1266 consequence of slab retreat.

1267

1268 **4.6. Late Carboniferous to Permian (c. 305-295 Ma) gravitational collapse and** 1269 **exhumation of the partially molten root of the Variscan orogenic belt**

1270

1271 The late Carboniferous (Figs. 13; 18e) is marked by regional scale extension of the Variscan belt of Western
1272 Europe (Ménard and Molnar, 1988), which is particularly illustrated in the French Massif Central by the activation

1273 of low-angle detachments (Bouilhol et al., 2006; Burg et al., 1993; Faure, 1995; Gardien et al., 1997; Malavieille
1274 et al., 1990; Van Den Driessche and Brun, 1992; Vanderhaeghe et al., 1999) controlling the exhumation of
1275 migmatites in the core of domes such as the Velay in the central-east French Massif Central (Burg and
1276 Vanderhaeghe, 1993; Dupraz and Didier, 1988; Ledru et al., 2001) and the Montagne Noire in the southern French
1277 Massif Central (Echtler and Malavieille, 1990; Gèze, 1949; Nicolas et al., 1977; Rabin et al., 2015; Trap et al.,
1278 2017; Van Den Driessche and Brun, 1992) (Fig. 3).

1279
1280 The HT/LP metamorphic conditions recorded by the migmatites coring the Velay and Montagne Noire domes and
1281 by the lower crustal granulites has been classically interpreted in terms of a sudden increase in temperature at the
1282 end of the Carboniferous (Barbey et al., 2015 ; Couzinié et al., 2013; Dupraz and Didier, 1988; Lardeaux et al.,
1283 2001; Ledru et al., 2001; Marignac et al., 1980). However, such a catastrophic event is not required by the data.
1284 Indeed, as discussed in the previous section, (i) the oldest ages obtained on migmatites in the Limousin and around
1285 the Velay and Montagne Noire domes, and (ii) the coeval emplacement of granitic plutons and vaugnerites
1286 indicates that the crust and the mantle were already partially molten as early as 340 Ma ago and remained so
1287 throughout the Carboniferous (Laurent et al., 2017; Vanderhaeghe et al., 1999). A similar time range has been
1288 proposed for the duration of the partial melting event in the Variscan crustal segment exposed in the Ivrea-Verbano
1289 Zone (Guergouz et al., 2018) but also for the root of the Grenville orogenic belt (Turlin et al., 2018). The
1290 continuous magma extraction from a partially molten source at depth results in the emplacement of granitic plutons
1291 (CPG, MPG) at higher structural level in combination with the entrainment of source material, which fully explains
1292 their chemical characteristics (Villaros et al., 2018). Final crystallization of migmatites is constrained by the ages
1293 of late-migmatitic dikes at c. 297 Ma in the Velay (Didier et al., 2013; Montel et al., 2002) and by the emplacement
1294 of a syntectonic granite at c. 294 Ma in the Montagne Noire (Poilvet et al., 2011).

1295
1296 The size of the Velay and Montagne Noire domes, i.e. several tens of km in diameter, indicates that they are
1297 crustal-scale features (Burg and Vanderhaeghe, 1993; Ledru et al., 2001; Van Den Driessche and Brun, 1992).
1298 This view of a pervasively partially molten orogenic root is corroborated by the diversity of the protoliths
1299 (orthoigneisses, paragneisses, amphibolites...) that have molten to form the migmatites (Barbey et al., 2015;
1300 Downes et al., 1997; Downes and Duthou, 1988; Ledru et al., 2001; Rabin et al., 2015; Williamson et al., 1992).
1301 Moreover, the fact that the domes are circumscribed by the foliation of the host paragneisses and orthogneisses
1302 (Lagarde et al., 1991; Echtler and Malavieille, 1990; Mattauer et al., 1995) and by the syn-melting foliation of the
1303 migmatites (Burg and Vanderhaeghe, 1993; Ledru et al., 2001; Rabin et al., 2015) indicates that the migmatites

1304 correspond to a mechanically coherent partially molten body. In the Velay, the synmigmatitic foliation delineates
1305 subdomes of about 10-20 km in diameter and bears a radially distributed HT mineral lineation pointing to the role
1306 of gravitational instabilities (Ledru et al., 2001; Vanderhaeghe, 2009). Such subdomes have been described in
1307 Naxos and interpreted as reflecting crustal-scale convection (Kruckenberg et al., 2011; Vanderhaeghe et al., 2018).
1308 In the Montagne Noire, migmatites in the core of the dome display a prolate finite strain ellipsoid indicative of
1309 constriction with a subhorizontal long axis parallel to the axis of the elliptical shape dome, which is coeval with
1310 exhumation of the dome's core (Echtler and Malavieille, 1990; Van Den Driessche and Brun, 1992; Mattauer et
1311 al., 1995; Aerden and Malavieille, 1999; Charles et al., 2009; Rabin et al., 2015). Following this rationale, the
1312 development of crustal-scale migmatite domes at 305-295 Ma marks the time at which the long-lived, partially
1313 molten lower-middle crust cooled rapidly as a consequence of rapid exhumation owing to gravitational collapse.
1314 If crustal thinning was faster than thermal relaxation, isothermal decompression of the migmatites would result in
1315 an increase of the geothermal gradient as observed in the E-FMC (Montel et al., 1992; Barbey et al., 1999, 2015;
1316 Ledru et al., 2001).

1317

1318 To explain the protracted melting of the root of the Variscan orogenic crust, one may invoke the effects of an
1319 increase in radioactive heat production of the thickened crust, combined with the increase in mantle heat flux
1320 owing to the southwards removal of the lithospheric mantle slab underneath the FMC. Coeval crustal thickening
1321 and lithospheric mantle thinning is the best case scenario to produce a high geothermal gradient in the continental
1322 crust (Vanderhaeghe and Duchêne, 2010) that might last for several tens of Myrs (Ueda et al., 2012). This model
1323 is also supported by the nature and spatial/temporal evolution of granitoid and vaugnerite magmatism (Moyen et
1324 al., 2017; Laurent et al., 2017). In addition to the thermal input at the base of the orogenic crust, partial melting
1325 might also be enhanced by exhumation, as dehydration melting reactions are crossed during decompression
1326 (Thompson and Connolly, 1995).

1327

1328 In the external zone of the Variscan belt, specifically in the Montagne Noire area, migmatites are present beneath
1329 and deform a metasedimentary sequence affected by recumbent folds and low-grade metamorphism. This is
1330 paradoxical as this scheme does not match the classical model of thermal relaxation after nappe stacking (Franke et
1331 al., 2011). Moreover, the deposition age of the protolith of part of the metasedimentary sequence (Visean to
1332 Namurian) overlaps with the geochronological record of HT/LP metamorphism and granitic intrusion, spreading
1333 from c. 330 to c. 300 Ma. In order to resolve this paradox, we propose that sediment deposition, HT/LP
1334 metamorphism and granite emplacement were indeed coeval but occurred in laterally remote units that were

1335 subsequently juxtaposed owing to lateral horizontal flow of the partially molten orogenic root beneath the
1336 sedimentary rocks and their upper crustal basement (Figs. 18e, 19). In this scenario, the migmatites coring the
1337 Montagne Noire dome represent partially molten rocks that were located beneath the orogenic plateau since the
1338 early Carboniferous and have flown laterally from the internal to the external zone in the late Carboniferous. The
1339 migmatites and associated granites were then exhumed, cooled and juxtaposed to the metasedimentary nappes
1340 along a detachment. The Variscan basement exposed in the Axial Zone of the Pyrenees and in the North Pyrenean
1341 Massifs displays similar geological features (Cochelin et al., 2017; de Saint Blanquat, 1993; Gleizes et al., 1997)
1342 and the partially molten orogenic root might have flown toward the foreland beneath the current day Pyrenees
1343 providing an explanation for their peculiar Carboniferous-Permian structural and metamorphic record.

1344
1345 Comparison between the eastern and the western part of the FMC, shows that large, late Carboniferous migmatite
1346 domes are only exposed in the eastern part of the FMC, which points to the Sillon Houiller as a major tectonic
1347 divide between these two parts of the FMC, at least during the late orogenic tectonic evolution. The Sillon Houiller
1348 corresponds to a subvertical sinistral strike-slip shear zone (Grolier and Letourneur, 1968; Arthaud and Matte,
1349 1975) cross-cutting the Lower to Middle Carboniferous transcurrent strike-slip shear zones. It is in places sealed
1350 by Visean volcanics, and localizes the deposition of late Carboniferous to Permian clastic sediments accompanied
1351 with the emplacement of rhyolite at the onset of extension (Bonijoly and Castaing, 1984; Joly et al., 2008, 2009;
1352 Lapierre et al., 2008; Thiéry et al., 2009). Scarce U-Pb data indicate an onset of deposition in some basins as early
1353 as 330 Ma (Bosmoreau and Decazeville Basins), but most ash beds yield ages of 300-295 Ma that constrain a
1354 predominance of syntectonic intramontane basins (Jaujac, Bosmoreau, Alès, Bertholène, Graissessac and Roujan-
1355 Neffies basins) during the late Carboniferous (Bruguier et al., 1998, 2003). In the Livradois, cooling of the
1356 migmatites and granites is recorded by argon thermochronology on micas and K-feldspar between 307 and 300
1357 Ma. It is associated with exhumation along a top-to the west low-angle detachment that controls the deposition of
1358 coal-bearing sediments in the Brassac basin (Gardien et al., 2011; Vanderhaeghe et al., 2013). The discordant
1359 contact of these deposits with the LGU (locally migmatitic) and UGU attest that these metamorphic units reached
1360 surface exposure at the end of Carboniferous and that exhumation and crystallization of the partially molten
1361 orogenic crust and of crustal melts was essentially terminated by 295 Ma.

1362
1363 In the western Massif Central, this period is marked by ductile-brittle detachments such as the Argentat fault that
1364 also accommodate a component of strike-slip displacement (Bellot and Roig, 2007). Accordingly, the activity of
1365 the Sillon Houiller straddles the transition from the orogenic plateau development to gravitational collapse of the

1366 Variscan belt. The limited lateral offset of the Sillon Houiller compared to its the length is consistent with its role
1367 as a transfer fault accommodating a larger amount of N-S extension in the eastern part of the French Massif Central
1368 relative to the western part (Burg et al., 1990). The presence of migmatite domes solely in the eastern part of the
1369 French Massif Central is consistent with this model. Currently, except for a slight variation beneath the Cenozoic
1370 rift, the continental crust displays a constant thickness of c. 30 km on both sides of the Sillon Houiller (Ziegler and
1371 Dèzes, 2006). This suggests that, at the time of orogenic gravitational collapse, the larger amount of surface
1372 extension in the eastern French Massif Central was compensated in the orogenic root by flow of the partially
1373 molten rocks from the northern and western French Massif Central toward the Velay and Montagne Noire dome
1374 in the southeastern part of the French Massif Central. Moreover, the presence of migmatites in the Montagne Noire
1375 and in the Pyrenees, beneath the foreland sedimentary sequence affected by recumbent folds and low-grade to
1376 HT/LP metamorphism, also suggests that the partially molten orogenic root has flown toward the foreland. This
1377 model provides a potential explanation for the enigmatic high geothermal gradient identified in the external zone
1378 and for propagation of crustal thickening in the foreland beneath supracrustal rocks. Our model is also compatible
1379 with the shallow northward plunge (0-30°) of the mineral and stretching lineation displayed along the Sillon
1380 Houiller (Grolier and Letourneur, 1968; Bonijoly and Castaing, 1984).

1381
1382 The P-T-t record of the lower crust documented by felsic and mafic granulitic xenoliths with a maximum pressure
1383 of 14 Kbar and a temperature of 900 °C followed by near isothermal decompression (Downes and Leyreloup, 1986;
1384 Leyreloup, 1974; Montel, 1985) is consistent with a hot and thick orogenic crust that has then been affected by
1385 thinning. U-Pb ages on zircon from the granulites from 320 to 280 Ma cover the transition from crustal thickening
1386 to gravitational collapse (Costa and Rey, 1995; Downes and Leyreloup, 1986). The geochemical characteristics of
1387 the granulites suggest that they represent a mixture of (i) resisters (rocks that were not prone to melt), (ii) solid
1388 residues after melt extraction, (iii) cumulates (iv) and residual melts (Downes et al., 1997; Dupuy et al., 1979; Pin
1389 and Vielzeuf, 1983; Vielzeuf et al., 1990), which is complementary to the evidences for crustal-derived magmas
1390 emplaced at higher structural levels. Such features are also identified in exposed sections of the Variscan lower
1391 crust in the Ivrea Zone (Barboza et al., 1999; Bea and Montero, 1999; Guergouz et al., 2018; Percival, 1992;
1392 Schaltegger and Gebauer, 1999) or in Calabria (Schenk, 1980, 1981, 1989).

1393

1394 **4.7. Pertinence of the proposed geodynamic-tectonic model compared to physical**
1395 **modeling of the dynamics of orogenic belts**

1396
1397 In this section, we assess the significance of the geological record of rocks forming the Variscan belt exposed in
1398 the French Massif Central in terms of the thermal-mechanical evolution of orogenic belts as investigated by
1399 physical modeling.

1400
1401 Eclogites, which are the oldest metamorphic rocks identified in the French Massif Central, and are present at the
1402 highest structural level of the nappe pile, have recorded HP/LT conditions. Such conditions imply burial at more
1403 than 30 km depth and more rapidly than the effect of thermal diffusion, typically a subduction rate of more than
1404 1 cm/yr (Henry et al., 1997; Huerta et al., 1996).

1405
1406 Modeling of the thermal evolution of orogenic belts has shown that a time delay of 20 to 30 Myrs after crustal
1407 thickening is required for thermal diffusion and heat production through natural decay of radioactive isotopes to
1408 lead to significant partial melting of the orogenic root (England and Thompson, 1984; Thompson and Connolly,
1409 1995). This 20 to 30 Myrs gap is consistent with the geochronological record of HT eclogites and granulites
1410 preserved in the UGU. In turn, the thermal impact of removal of the lithospheric mantle root is more rapid and
1411 dramatic in terms of increase in temperature in the crust (Arnold et al., 2001; Houseman et al., 1981). Thinning of
1412 the lithospheric mantle is so efficient that it has been proposed as a mechanism to account for HT/LP
1413 metamorphism in back-arc basins marked by a relatively thin crust (Collins, 2002). In the case of a convergent
1414 plate boundary marked by slab retreat and tectonic accretion, both the radioactive heat production and the mantle
1415 heat flux are increased concomitantly, which is the most favorable scenario for a hot orogenic root (Arnold et al.,
1416 2001; Sandiford and Powell, 1990; Vanderhaeghe and Duchêne, 2010). In such a case, thermal relaxation after
1417 removal of the lithospheric mantle occurs over about 100 Myrs (Ueda et al., 2012), which is roughly the duration
1418 of HT metamorphism and magmatism invoked in the geodynamic-tectonic model presented in this paper.

1419
1420 Exhumation of rocks entrained in subduction entails mechanical decoupling of these rocks from the downgoing
1421 slab, which in turns indicates that their buoyancy reached their mechanical strength (Chemenda et al., 1996; Escher
1422 and Beaumont, 1997; Warren et al., 2008). In turn, partial melting might particularly efficient in decreasing the
1423 strength of buried rocks and thus favouring their decoupling from the downgoing slab and their exhumation.

1424

1425 The presence of a low-viscosity orogenic root is causing horizontal flow of the thickened crust (Artyushkov, 1973;
1426 Bird, 1991; Molnar and Lyon-Caen, 1988; Royden, 1996). This horizontal flow, driven by the gravity force
1427 associated with lateral variations of the weight of the crustal column, occurs preferentially toward a free boundary
1428 or a mechanically weak zone. In the case of an advancing plate boundary, i.e. indentation, horizontal flow occurs
1429 preferentially laterally and is associated with the activation of strike-slip shear zones (Cagnard et al., 2006; Royden,
1430 1997). The low-viscosity layer might also flow in the direction of convergence, toward the foreland (Henk, 2000;
1431 Vanderhaeghe et al., 2003). The presence of a low-viscosity layer also impedes the maintenance of an irregular
1432 topographic surface (Artyushkov, 1973), which leads to the formation of an orogenic plateau (Molnar et al., 1993;
1433 Vanderhaeghe et al., 2003). If the zone of weak crust is maintained along its boundaries by stronger crustal sections,
1434 the orogenic plateau might be maintained (Cook and Royden, 2008; Vanderhaeghe et al., 2003). In the contrary,
1435 horizontal flow of the low-viscosity orogenic root will lead to redistribution of the orogenic crust until total decay
1436 of the gravity force (Rey et al., 2001). The style of extension is controlled by the rheology of the crust and thus its
1437 temperature (Buck, 1991; Rey et al., 2009).

1438

1439 Given its low density and low viscosity, a partially molten orogenic root is susceptible to develop diapiric
1440 Rayleigh-Taylor instabilities (Cruden et al., 1995; Perchuk et al., 1992; Ramberg, 1968; Talbot, 1979; Weinberg
1441 and Schmeling, 1992) and even convective instabilities (Vanderhaeghe et al., 2018; Weinberg, 1997).

1442 **5. Conclusion**

1443

1444 The structural, petrological, geochemical and geochronological record of the French Massif Central provides an
1445 archive of the thermal-mechanical evolution of the Variscan belt in Western Europe and documents the impact of
1446 partial melting and magmatism during orogenic evolution, as summarized in the following and in Figures 18 and
1447 19.

1448

1449 The pre-Variscan paleogeography (Figs. 16, 17) is marked by hyper-extension of the northern margin of the
1450 Gondwana supercontinent, evidenced by the coeval emplacement of alkaline granitoids and of tholeiitic to calc-
1451 alkaline bimodal mafic-felsic magmas of the Leptynite Amphibolite Complex during Ordovician times (485-460
1452 Ma). This setting is particularly favorable for trapping of voluminous detrital sediments and the emplacement of
1453 alkaline magmas that might represent the protoliths of the main portion of the metagreywackes, metapelites and
1454 orthogneisses forming the UGU, MAU, LGU and PAU.

1455

1456 The presence of HT eclogite facies mafic and ultramafic enclaves of the Leptynite Amphibolite Complex into the
1457 migmatitic HP granulites of the UGU indicates subduction of the immature oceanic crust (Fig. 18a) together with
1458 continental ribbons (Fig. 18b). The 20-30 Ma difference in age between the eclogite-facies metamorphism
1459 recorded by the LAC corresponds to the time required for thermal relaxation and partial melting. Partial melting
1460 potentially triggered decoupling of the UGU from the downgoing slab allowing for the syn-orogenic exhumation
1461 of the partially molten UGU entraining pieces of mafic and ultramafic rocks forming the LAC and representing
1462 previously subducted oceanic lithosphere and/or part of the suprasubduction mantle. The percolation into the
1463 suprasubduction mantle of felsic melt segregated from the partially molten UGU would have possibly contributed
1464 to its enrichment in HFSE, REE and LILE required to form the source of the later vaugnerites.

1465
1466 During the Devonian-Carboniferous transition, opening of a rift in the internal zone of the Variscan belt is
1467 accompanied by the emplacement of the c. 360 Ma ACG and low-K calc-alkaline to tholeiitic magmas of the
1468 Brévenne Unit and Limousin tonalitic line. This is coeval with thrust propagation in the external zone and
1469 deposition of detrital sediments in the foreland that we tentatively attribute to the outward propagation of the
1470 orogenic belt in a context of slab retreat (Fig. 18c). Such a context might have facilitated syn-orogenic exhumation
1471 of the buoyant and low-viscosity partially molten felsic units previously dragged with the subducting slab.

1472
1473 Regional scale transcurrent shear zones and foreland propagation of thrusts accommodate the development of an
1474 orogenic plateau by gravity-driven lateral flow of the partially molten orogenic root, owing to a major
1475 Carboniferous thermal anomaly of lithospheric extent. This is indeed associated with high-temperature/medium-
1476 pressure metamorphism and the emplacement of syntectonic plutons from 345 to 310 Ma (Fig. 18d). The diversity
1477 of the geochemical signatures of the magmatic rocks encompassing MPG, CPG and their volcanic equivalents,
1478 KCG and Mg-K vaugnerites indicates a contribution of both the crust and the mantle. The latter along with the
1479 southward younger emplacement ages of these magmatic rocks is consistent with progressive retreat toward the
1480 south of the northward plunging slab during the Carboniferous.

1481
1482 The late Carboniferous gravitational collapse of the Variscan orogenic crust (Fig. 18e) is accommodated by
1483 extension of the upper crust and by lateral flow and exhumation of the partially molten root. This is marked by the
1484 formation of crustal-scale domes cored by LP migmatites and heterogeneous granites coeval with the emplacement
1485 of syntectonic laccoliths in the footwall of low-angle detachments. These are complementary to a refractory

1486 granulitic lower crust formed by protracted high-temperature metamorphism, partial melting and melt/solid
1487 segregation.

1488

1489 According to this new model consistent with physical modeling, continuous and protracted presence of melt in the
1490 root of the orogenic crust plays a crucial role in the tectonic evolution of the Variscan belt by (i) triggering syn-
1491 orogenic exhumation of subducted continental units decoupled from the downgoing slab; (ii) controlling the
1492 formation and lateral development of an orogenic plateau; and finally, (iii) guiding the formation of metamorphic
1493 core complexes during orogenic gravitational collapse. Crustal melting starts with segregation of melts from the
1494 subducted oceanic and continental units in the Devonian. Subsequently during the Carboniferous, the emplacement
1495 of plutons and volcanics during the building of the orogenic plateau has a contribution from the partially molten
1496 crust and from the mantle. The maintenance of a partially molten crust for several tens of Ma is probably favored
1497 by the combined effects of radioactive heat production and increasing mantle heat flux owing to removal of the
1498 lithospheric mantle slab. It ended with the extraction of differentiated magmas and crystallization of the collapsed
1499 partially molten orogenic root. The contrasting Carboniferous geological record between the Western and Eastern
1500 French Massif Central separated by the Sillon Houiller is consistent with a more pronounced slab retreat in the
1501 East toward the Paleotethys free boundary. The Eastern part of the French Massif Central is indeed characterized
1502 by (i) the abundance of Mg-K diorites (vaugnerites) and KCG-type granites indicating the contribution of mantle-
1503 derived magmas, and (ii) a widespread extension associated with the development of the Velay and Montagne
1504 Noire migmatite domes (Fig. 19).

1505

1506 **Acknowledgments**

1507

1508 This paper results from a long gestation process. First or all, Olivier Vanderhaeghe is evry grateful to Patrick Ledru
1509 and Jean-Michel Caron for their initiation to the geology of the Massif Central Français and also to Jean-Pierre
1510 Burg for his encouragements in developing the structural analysis of migmatites. The authors address a special
1511 thank to Philippe Rossi, director of the French geological mappint program, and the BRGM for financial support
1512 at different stages. Arnaud Villaros acknowledges financial support from the Labex VOLTAIRE (ANR-10-LABX-
1513 100-01) and Jean-François Moyon, Simon Couzinié and Arnaud Villaros were supported by credits from the INSU
1514 2016 Syster program.

1515 A first version of this manuscript, submitted to an IJES special volume following the Variscan 2015 conference,
1516 has benefitted from the stimulating viewpoint of Roberto Weinberg and from the critical opinion of an anonymous

1517 reviewer. As a result, the present version was considerably augmented and was itself significantly improved owing
1518 to the constructive review of Jacques Malavieille and from the challenging comments of an anonymous reviewer
1519 not sharing the same vision of this segment of the Variscan belt. The authors thank Olivier Averbuch and Laurent
1520 Jolivet for their careful and balanced editorial handling.

1521

1522 **Figure Captions**

1523

1524 **Figure 1.** Tectonic map of the Variscan belt in Western Europe. Continental terranes, Avalonia, Saxo-Thuringia,
1525 Armorica-Barandia, Brunia, are separated by ophiolitic sutures, namely the Rheic suture and the Medio-European
1526 suture, to the north and south of Armorica respectively. The internal zone of the Variscan belt comprises high-
1527 grade nappes overlying a parautochthonous unit belonging to the northern margin of Gondwana.

1528

1529 **Figure 2.** Geodynamic-tectonic models and paleogeographic reconstructions for evolution of the Variscan belt of
1530 Western Europe. a) The double subduction model (modified after Matte, 1986; 1991; 2001). b) The polycyclic
1531 model (modified after Faure et al., 1997; 2002; 2009 and Lardeaux et al., 2014). c) Single (Rheic) Ocean model
1532 of Paris and Robardet (1990); Martinez Catalan et al. (2001); Nance (2010). d) Multiple Oceans (Rheic, Medio-
1533 European, ...) model of Tait et al. (1997); Matte (2001); Stampfli and Borel (2004); Domeier and Torsvik (2014).

1534

1535 **Figure 3.** Geological map of the French Massif Central (modified after Chantaine et al., 2003). Metamorphic
1536 rocks comprise (i) a low-grade metasedimentary sequence attributed to the Lower Paleozoic (Cambrian to Lower
1537 Carboniferous), (ii) micaschists and paragneisses of uncertain age but considered as Neoproterozoic to Lower
1538 Paleozoic deposits, (iii) orthogneisses with a Cambrian or Ordovician age. The Middle Allochthonous Unit, the
1539 Parautochthonous Unit and the Lower Gneiss Unit are made of these metasedimentary rocks and orthogneisses. The
1540 Upper Gneiss Unit is characterized by relics of granulite facies metamorphism and by enclaves-boudins of mafic
1541 and ultramafic rocks affected by eclogite facies metamorphism, designated as the Leptynite-Amphibolite Complex
1542 (LAC). The color scheme of magmatic rocks is indicative of their age. Granitoids are distinguished according to
1543 their petrologic types in figure 6.

1544

1545 **Figure 4.** Synthetic P-T-t paths of the Upper Gneiss Unit, Middle Allochthonous Unit, and of the Lower Gneiss
1546 Unit. The Upper Gneiss Unit is made of granulitic migmatites enclosing mafic and ultramafic enclaves of the
1547 Leptynite-Amphibolite Complex, whereas the Middle Allochthonous is not migmatitic. a) The Leptynite-

1548 Amphibolite Complex contains UHP and eclogitic relics dated at the transition from late Silurian to late Devonian
1549 as indicated by the numbers in the circles (c. 432 to c. 377 Ma). b) These rocks are retrogressed into the granulite
1550 facies dated from the middle to the late Devonian (c. 384 to c. 360 Ma) in the migmatitic gneisses of the Upper
1551 Gneiss Unit. c) The Lower Gneiss Unit comprises rare HP/LT rocks in the Limousin dated at c. 376 Ma. Rocks of
1552 the Lower Gneiss Unit have also recorded early Carboniferous (348-320 Ma) and late Carboniferous (304-302 Ma)
1553 LP amphibolite facies metamorphism.

1554
1555 **Figure 5.** Geochronological constraints on the emplacement and deposition ages of pre-Variscan rocks. For
1556 orthogneisses, the emplacement age corresponds to the Rb-Sr whole rock isochron age (circles) or the the youngest
1557 U-Pb, U-Th-Pb age obtained on magmatic zircon or monazite. For paragneisses, a maximum deposition age is
1558 provided by the youngest inherited age. Cambrian and Ordovician orthogneisses do not appear associated with a
1559 given nappe but are found throughout the French Massif Central.

1560
1561 **Figure 6.** Petrology of granitoids of the French Massif Central. Plutons are distinguished on the basis of the
1562 petrology of their dominant facies according to the classification of Barbarin (1999). ACG-type (alkaline granites)
1563 are interpreted as arc magmas originated in an Andean-type continental margin by partial melting of an enriched
1564 mantle contaminated by the crust of the upper plate and/or mixed with crutal magmas. MPG-type (or muscovite-
1565 bearing peraluminous granites) are attributed to muscovite dehydration- or water present melting of a dominantly
1566 metasedimentary source. CPG-type (or cordierite-bearing peraluminous granites) are attributed to biotite
1567 dehydration melting of orthogneisses. KCG-type (or K-rich calc-alkaline granites) typically contain abundant
1568 micromafic enclaves and are attributed to mixing between magmas generated by partial melting of the crust and a
1569 magma with a magma generated by partial melting of an enriched lithospheric mantle represented by Mg-K diorites
1570 (the so-called vaugnerites).

1571
1572 **Figure 7.** Cross sections depicting the previously proposed nappe structure. a) Multiple sutures-nappe model
1573 (modified after Burg and Matte, 1978). b) Single suture model associated with a basement duplex structure (Matte,
1574 1991). c) Single suture model associated with a stack of three nappes and an “unknown Porteorzoic basement”
1575 (Faure et al., 2009).

1576
1577 **Figure 8.** Cross sections of the French Massif Central. The location of the cross sections (A-A', B-B', C-C', and
1578 D-D') is indicated on the geological map figure 2. Same legend as figure 3 with the addition of a granulitic lower

1579 crust intruded by mantle-derived mafic magmas. The upper part of the sections is constrained by field observations.
1580 The shaded lower part of the sections is less constrained and is based on scarce geophysical data that allow the
1581 prolongation of some structures at depth and on exposed sections of the Variscan lower crust in the Southern Alps
1582 (Ivrea Zone) and in Calabria.

1583
1584 **Figure 9.** P-T-t constraints on the metamorphic history of the Upper Gneiss Unit and of the Middle Allochthonous
1585 Unit. The Leptynite-Amphibolite Complex is characterized by HT eclogite facies metamorphism retrogressed into
1586 granulite facies by isothermal decompression and then into amphibolite facies by a decrease in temperature.
1587 Granulite facies to amphibolite facies metamorphism is also recorded in the migmatitic gneisses hosting the LAC.
1588 The PT path is depicted by the white arrows and numbers correspond to radiometric ages.

1589
1590 **Figure 10.** P-T-t constraints on the metamorphic history of the Lower Gneiss Unit. The P-T-t paths of
1591 orthogneisses and paragneisses of the LGU indicate first an increase in temperature followed by isobaric cooling.
1592 This is particularly well illustrated by the P-T-t path of the south Velay which is characterized by a HT/LP gradient.
1593 The PT path is depicted by the white arrows and numbers correspond to radiometric ages.

1594
1595 **Figure 11.** Late Devonian to Early Carboniferous magmatism. The western part of the French Massif Central is
1596 dominated by plutonic rocks of the ACG-type and CPG-type while the eastern part of the French Massif Central
1597 also comprises volcanics with a tholeiitic to calc-alkaline signature.

1598
1599 **Figure 12.** Middle Carboniferous magmatism. Magmatic rocks with ages ranging from c. 345 to c. 310 Ma are
1600 widespread throughout the northern part of the French Massif Central indicating the presence of a partially molten
1601 source at depth during this period. Plutonic rocks display a variety of geochemical signatures encompassing MPG-
1602 type, CPG-type, and KCG-type pointing to the contribution of crustal and mantle sources.

1603
1604 **Figure 13.** Late Carboniferous-Permian magmatism. Magmatic rocks with ages ranging from c. 305 to c. 295 Ma
1605 are localized along the Sillon Houiller and are present as plutons and in the core of large migmatite domes (Velay,
1606 Montagne Noire) in the eastern part of the French Massif Central. The presence of plutonic rocks to the south of
1607 the French Massif Central suggests that the partially molten source has migrated since the Lower Carboniferous
1608 from the internal to external zone of the Variscan belt. The combination of MPG-type, CPG-type and KCG-type
1609 granites emplaced during this period is consistent with the contribution of crustal and mantle sources and is

1610 interpreted as reflecting the impact of southward slab retreat that is more pronounced beneath the eastern part of
1611 the French Massif Central.

1612

1613 **Figure 14.** Geochemistry of magmatic rocks of the French Massif Central. a) Two mantle sources in the Massif
1614 Central (calculated at 315 Ma, an average between the c. 335 Ma lavas and the ca 305 Ma lamprophyres and
1615 vaugnerites): note the clear difference between the pre-335 mafic magmas (lavas from the Brévenne Unit (Pin and
1616 Paquette, 1998) and diverse lavas from NE Massif Central (Pin and Paquette, 2002)), and the post-335 Ma lavas
1617 (lamprophyres: (Agranier, 2001); enclaves in granites (Pin et al., 1990) and vaugnerites (Williamson et al., 1992);
1618 underplated mafic magmas (or cumulates) found as enclave in the Cenozoic Bournac volcano (Downes et al.,
1619 1990)). b) Change in the nature of the lavas, in Shand (1943) A/CNK vs. A/NK and Peccerillo & Taylor (1976)
1620 SiO₂ – K₂O diagrams. Pre-335 Ma lavas are mafic and metaluminous, whereas post-335 Ma lavas are felsic, high-
1621 K and peraluminous, essentially similar to MPG granites forming at the same age.

1622

1623 **Figure 15.** Geochemical characteristics of magmatic rocks exposed in the East French Massif Central. Summary
1624 of the geochemical characteristics of E-FMC granitoids, in a A/CNK (molar Al₂O₃/CaO+Na₂O+K₂O diagram,
1625 Shand 1943) vs. FSMB ((FeO+MgO)*(Sr(wt.%)+Ba(wt.%))) diagram (Laurent et al. 2014). This diagram
1626 separates granitoids related to different sources (Moyen et al. 2017), and shows that KCG are primarily related to
1627 the differentiation of vaugnerites (with minor crustal components occasionally); MPG are related to a
1628 metasedimentary source; CPG are generated from a source dominated by orthogneisses, but with more common
1629 involvement of either a metasedimentary component (particularly pronounced in the Velay complex) or a mafic
1630 component (e.g. the Margeride granite).

1631

1632 **Figure 16.** Pre-Variscan geodynamic configuration. a) During the Cambrian, the Gondwana margin is marked by
1633 the emplacement of calc-alkaline magmas attributed to an enriched mantle source above a subducting slab. The
1634 size of the Iapetus is about 2000-3000 km wide. b) During the Ordovician, the Avalonia and Armorica continental
1635 ribbons are separated from the Gondwana margin. The Rheic Ocean corresponds to the future Rheic suture exposed
1636 in southern Great Britain. The Medio-European Ocean corresponds to the Leptynite-Amphibolite Complex
1637 forming boudins and enclaves in high-grade nappes of the Moldanubian allochthonous terrane (see figure 3). The
1638 tholeiitic to calc-alkaline signature of the LAC is interpreted as reflecting an emplacement of the magmatic
1639 protoliths in a back-arc or immature oceanic setting. Alkaline magmas intrusive in Ediacarian sedimentary
1640 sequences correspond to orthogneisses preserved in the LGU and PAU and are attributed to opening of a series of

1641 rifts leading to hyperextension of the Gondwana margin. These features are consistent with retreat of the southward
1642 plunging Iapetus slab that will eventually lead to tectonic accretion of Avalonia to the Laurussia craton.

1643

1644 **Figure 17.** Plate scale geodynamic reconstruction for the Paleozoic (modified after (Domeier, 2016; Domeier and
1645 Torsvik, 2014; Matte, 2001). a) Cambrian 500 Ma (541-485 Ma). The Gondwana margin is at the South Pole,
1646 Laurentia is at the Equator and the Iapetus Ocean is at least 3000 km wide. The Gondwana margin is an active
1647 plate boundary marked by subduction of the Iapetus. b) Ordovician 470 Ma (485-444 Ma). The margin of
1648 Gondwana is marked by hyperextension resulting in the separation of Avalonia and Armorica and the opening of
1649 the Rheic and Medio-European Oceans. c) Silurian 430 Ma (444-419 Ma). The Iapetus Ocean has closed and
1650 Avalonia has been tectonically accreted to Laurussia. The Rheic Ocean started to subduct beneath the margin of
1651 Laurussia and Medio-European Ocean, between Armorica and Gondwana is at its maximum width. d) Devonian
1652 380 Ma (419-359 Ma). Armorica is bounded by subduction zones with opposite vergence resulting in the formation
1653 of the Variscan belt. e) Carboniferous 330 Ma (359-299 Ma). The Variscan orogenic front progresses from the
1654 hinterland to the foreland in association with slab retreat.

1655

1656 **Figure 18.** Geodynamic-tectonic model of the Variscan belt exposed in the French Massif Central. a) Silurian (c.
1657 420 Ma) subduction of the Medio-European Ocean. b) Middle Devonian (c. 385 Ma) subduction and partial
1658 melting of the hyper-extended northern continental margin of the Gondwana craton. c) Late Devonian (c. 365 Ma)
1659 slab retreat, opening of the Brévenne rift and syn-orogenic exhumation of high-grade partially molten nappes. d)
1660 Lower Carboniferous (c. 330 Ma) development of an orogenic plateau by lateral flow of partially molten orogenic
1661 root in a context of plate convergence and southward slab retreat. e) Late Carboniferous (c. 300 Ma) gravitational
1662 collapse of the Variscan belt in a context of southward slab delamination accommodated by lateral and upward
1663 flow of the partially molten orogenic root concomitant with brittle extension of the upper crust.

1664

1665 **Figure 19.** 3D model for the late Carboniferous crustal and lithospheric scale structure of the Variscan belt beneath
1666 the French Massif Central. Gravitational collapse is accommodated by (i) lateral flow of the partially molten
1667 orogenic root from the western to the eastern side of the French Massif Central and from the internal to the external
1668 zone toward the south, and (ii) upward flow to form migmatite domes within Metamorphic Core Complexes. The
1669 Sillon Houiller accommodates differential slab retreat between the eastern and western parts of the French Massif
1670 Central.

1671

1672
